Although there are reports of the possibility of erythromycin-resistant strains of *T. pallidum* (Stapleton et al. 1985), antimicrobial susceptibility testing is not straightforward because there is no method for the continuous culture of *T. pallidum*. Various approaches have been used to determine the susceptibilities of representative strains (e.g. the Nichols strain) to antimicrobial agents, including in vitro loss of motility or infectivity, treatment of experimental animal infections, human trials, and examination of the susceptibility of nonpathogenic, cultivable treponemes (Rein 1976). Inhibition of protein synthesis and of in vitro multiplication in a tissue culture system has been shown to be an effective means of determining susceptibility (Stapleton et al. 1985; Norris and Edmondson 1988). In common with other spirochetes, *T. pallidum* was relatively insensitive to seven quinolones tested and to rifampicin. *T. pallidum* strains appear to be uniformly susceptible for penicillin and other β-lactams tested. Ceftriaxone, amoxycillin, and ampicillin are active against *T. pallidum* in vitro and also appear to be effective in the treatment of early syphilis. Amoxycillin and ampicillin offer no theoretical advantages over benzathine penicillin G. Ceftriaxone has a long serum half-life and reaches high levels in the CNS. However, the cost is high, multiple doses are required, and there is a 3–7 percent risk of adverse reactions in penicillin-allergic individuals; in addition, the data on efficacy in patients are limited. Therefore, ceftriaxone is not currently recommended as an alternative therapy for early syphilis. Recent studies have indicated that azithromycin may have utility in treating incubating syphilis (Hook et al. 1999) and early syphilis (Hook et al. 2002). However, there have been recent reports of Azithromycin resistance in *T. pallidum* so caution should be used when treating incubating syphilis using this antimicrobial (Lukehart et al. 2004).

Evaluation after therapy

To follow the efficacy of therapy, patients should be monitored to ensure that signs and symptoms have resolved and that the nontreponemal antibody titer has declined. To monitor the efficacy of treatment, quantitative nontreponemal tests should be performed on the patient's serum samples, which are drawn at intervals of 3 months for at least 1 year. Following adequate therapy for initial episodes of primary and secondary syphilis, there should be at least a four-fold decline in the VDRL titer by the third or fourth month and an eight-fold decline in titer by the sixth to eighth month (Brown et al. 1985). When the RPR card test is used to monitor treatment, the initial four-fold decline in titer may not be observed until the sixth or eighth month following treatment (Romanowski et al. 1991). For most patients treated in early syphilis, the titers decline until little or no reaction is detected after the first 3 years (Fiumara 1978, 1980b; Romanowski et al. 1991). Patients treated in the latent or late stages, or who have had multiple episodes of syphilis, may show a more gradual decline in titer (Fiumara 1979, 1980a). A low titer will persist in approximately 50 percent of these patients after 2 years. As far as can be determined, this persistent seropositivity does not signify treatment failure or reinfection and these patients are likely to remain serofast even if they are retreated.

RELATED TREPONEMES

Yaws, endemic syphilis (bejel), and pinta were common infections before the World Health Organization eradication program that began in 1948. In the early 1950s, it was estimated that more than 200 million people had been exposed to yaws. Areas where the nonvenereal treponematoses are endemic are now more restricted, but decreased surveillance has led to a return of these diseases in many areas. Therefore, the clinical appearance of the lesions formed by *T. pallidum* subspecies *pertenue*, *pallidum*, *endemicum*, and *Treponema carateum*, the anatomical location of the lesion, the mode of transmission, the age of the individual, and the geographical location of the infected individual are the only criteria that can be used to diagnose these infections as separate entities (Perine et al. 1984; Chin 2000) (Table 1). This is especially important because none of the serologic tests for syphilis can distinguish between the diseases caused by the pathogenic treponemes.

Bejel

The lesions of bejel (endemic syphilis), associated with primitive, crowded, and unhygienic conditions, develop after an incubation period of 2 weeks to 3 months. Mucous patches of the mouth usually occur first, followed by moist papules in folds of the skin, and drier lesions of the trunk and extremities. A primary sore is rarely evident. Both depigmentation and hyperpigmentation are common. The late manifestations include destructive lesions of skin, long bones, and nasopharynx similar to gummas of late syphilis (Perine et al. 1984; Chin 2000). However, neurological, cardiovascular, and congenital forms are rarely reported. The disease was once common among children living in poor socioeconomic conditions in the arid regions of the eastern Mediterranean, Asia, and Africa. Bejel still persists in

Chad, Sudan, and Ethiopia and rarely in southern Africa (Meheus and Antal 1992).

Yaws

The primary lesion of yaws, commonly referred to as the mother yaw, occurs following an incubation period of 2 weeks to 3 months. This initial lesion is a papilloma located on the face or extremities. The lesion may slowly proliferate to form a frambesial or raspberry-like lesion or the initial lesion may ulcerate. Secondary lesions of disseminated or satellite papillomata (daughter yaws) form in successive eruptions (crops), with the first crop appearing either before or shortly after the mother yaw has resolved. Other symptoms accompanying the secondary lesions include aching of long bones and inflammation of the fingers and toes. Papillomata and hyperkeratoses that form on the soles and palms are usually very painful and disabling. These lesions heal spontaneously but relapses may occur during the secondary or late phases. The late stage develops in approximately 10 percent of untreated patients. The stage is characterized by destructive lesions of the skin and bones (Perine et al. 1984; Chin 2000). Congenital yaws has not been documented; controversy exists over the occurrence of neurological and cardiovascular forms (Engelkens et al. 1991a). Today, yaws is primarily a disease of children living in the tropical areas of central and west Africa (Meheus and Antal 1992). Some small foci of disease remain in the Americas and on islands of the Caribbean (Meheus and Antal 1992).

Pinta

Perhaps the most distinctive lesions of the pathogenic treponematoses are observed in pinta. First, a primary scaling papule forms 1–8 weeks after infection on the hands, legs, or the back of the foot. Within 3 months to 1 year, a maculopapular, erythematous secondary rash appears that may evolve into tertiary splotches of altered skin pigmentation. Initially the macules are blue, progressing to violet, and then brown, and finally becoming depigmented after months to years. Treponemes are found in the pigmented lesions; the achromic scars are usually free of treponemes. The lesions of the secondary rash most commonly progressing to the late form are frequently found on the face and extremities; lesions in different stages of pigmentation can be observed simultaneously (Perine et al. 1984; Chin 2000). Systemic infection with organ or bone involvement apparently does not occur. Pinta is predominantly a disease found among older children and adults living in the Indian tribes of Mexico and the Amazon basin (Meheus and Antal 1992). Because of the location of the primary lesion, trauma is suspected of providing the portal of entry for the treponemes. Direct and prolonged contact with initial, secondary, and early tertiary lesions appears to be necessary for transmission to take place; however, the mode of transmission is not entirely clear (Engelkens et al. 1991b).

Because yaws, pinta, and nonvenereal syphilis are often childhood diseases, the nontreponemal test titers of adults are expected to be $\leqslant$1:8 for those from a geographical region where endemic treponematoses were virtually eliminated by mass campaigns in the 1950s and 1960s (Antal and Causse 1985; Meheus and Antal 1992). Therefore, any titer >8 is suggestive of venereal syphilis for adults from these regions (Gershman et al. 1992; McDermott et al. 1993). Likewise a titer $\geqslant$8 in a child suggests a resurgence of endemic treponematoses in these particular areas (Perine et al. 1985).

Oral spirochetes

Various spirochetes inhabit supragingival and subgingival plaque in humans; only a small proportion of these have been cultured in vitro and characterized (Choi et al. 1994). Those that have been cultivated and identified to species level are within the genus *Treponema*. Although the species differ from one another slightly in terms of cell diameter and helical configuration, it is generally not possible to identify them on morphological grounds. Biochemical parameters such as growth requirements, carbohydrate fermentation, and enzymatic activities have been used for identifying species (Smibert et al. 1984).

The oral spirochetes are difficult to isolate from healthy gingiva, but they increase both in prevalence and in numbers of organisms present in patients with gingivitis or periodontal disease. Treponemes are detected in subgingival plaque of 88–97 percent of patients with periodontal disease (Moore et al. 1987). *Treponema socranskii* is the most common isolate, followed by *T. denticola* and *Treponema pectinovorum*. The procedures for isolation and characterization of oral spirochetes have been described previously (Smibert and Burmeister 1983; Smibert 1984; Smibert et al. 1984; Moore et al. 1987; Miller et al. 1992). Pathogen-related oral spirochetes (PROS) were found in plaque samples from 11 of 17 patients with necrotizing ulcerative gingivitis and from 10 of 19 patients with periodontitis, but were absent from 24 healthy subjects (Riviere et al. 1991a, 1991b, 1991c; Simonson et al. 1993). PROS have not been cultured in vitro and are identified by their reactivity with monoclonal antibodies specific for *T. pallidum* antigens, including the 35-kDa flagellar sheath protein and a major 47-kDa lipoprotein. Gingivitis and periodontis patients also expressed IgG antibodies reactive with 47-, 27-, 14-, and 12-kDa *T. pallidum* subspecies *pallidum* antigens, whereas a smaller proportion of

healthy subjects had detectable antibodies against only the 47- and 37-kDa antigens (Riviere et al. 1991c). PROS were found in periodontal tissues of ulcerative patients (Riviere et al. 1991b, 1991c) and were capable of migrating through a mouse abdomen wall barrier, an invasive property shared with *T. pallidum* but not with the cultivable oral treponemes (Riviere et al. 1991a). Oral spirochetes reactive with anti-*T. pallidum* monoclonal antibodies were also detected in gorillas and dogs (Simonson et al. 1993). Further studies are in progress to establish the taxonomic relationship between PROS and other spirochetes and to determine whether PROS represent frank pathogens.

Nonpathogenic spirochetes of the genital region

T. phagendenis, *T. refringens*, and *Treponema minutum* are treponemal species that inhabit smegma (sebaceous secretions and desquamated epithelial cells), which is found beneath the prepuce and in other epithelial folds of the genital region. Although *T. phagendenis* and *T. refringens* have been shown by DNA–DNA hybridization to have $\leqslant$5 percent homology with *T. pallidum* (Fieldsteel 1983), comparison of 16S rRNA sequences has indicated that they are related to the pathogenic treponemes. These harmless flora could potentially be misidentified as *T. pallidum* in darkfield preparations from skin sites. Unlike the pathogenic treponemes, these non-pathogenic treponemes are readily cultured (Miller et al. 1992).

THE GENUS *LEPTOSPIRA* AND ITS SPECIES, AND THE ASSOCIATED GENERA *LEPTONEMA* AND *TURNERIA*

The genus *Leptospira* comprises morphologically similar thin helical bacteria (spirochetes). The trivial name used for all members of the genus is leptospira or leptospire (plural leptospires). All are similar morphologically and culturally, but can be grouped serologically by agglutinating antigens into characteristic serovars. More than 200 serovars are recognized. One major serological complex containing most of the leptospires known or suspected to be pathogenic was named the 'interrogans complex'. Later, it became the broad, serologically determined species '*Leptospira interrogans*'. The other major group, containing nonpathogenic leptospires, was previously known as the 'biflexa complex' and was later designated '*L. biflexa*'. The genera *Leptonema* and *Turneria* were first recognized because the type strains were morphologically different from other leptospires. DNA homology studies justified this classification. The leptospires were comprehensively reviewed by Faine et al. (1999).

Definitions

FAMILY AND GENUS

The family Leptospiraceae includes the genera *Leptospira*, *Leptonema*, and *Turneria*, a group of bacteria that separated very early in bacterial evolution (Paster et al. 1984, 1991; Paster and Dewhirst 2000). Characteristically, all members are motile, flexible, helical aerobic bacteria, 6–12 μm long or longer and 0.1 μm in diameter (Johnson and Faine 1984a, b). There is no constant morphological characteristic of each genus, but *Turneria* tends to be shorter. Typically, one or both ends are hooked, but straight variants occur. The helical cell body (cytoplasmic cylinder) is wound around a pair of periplasmic flagella arising from it subterminally, one at each end. The diamino acid in the peptidoglycan is α,ε-diaminopimelic acid. Long chain fatty acids or fatty acid alcohols are used as carbon and energy sources. The guanine + cytosine (G + C) ratio is 35–53 mol%. The formal description of the genus *Leptospira* states that it is gram-negative but difficult to visualize, and oxidase-positive and chemoorganotrophic. It also includes some of the further

information discussed below (Faine and Stallman 1982; Johnson and Faine 1984a).

THE SPECIES OF *LEPTOSPIRA*

The species of leptospires are differentiated by DNA homology under high stringency conditions. Currently, ten named species of leptospires (*alexanderi*, *borgpetersenii*, *fainei*, *inadai*, *interrogans*, *kirschneri*, *meyeri*, *noguchii*, *santarosai*, and *weilii*) are recognized in the 'pathogenic' group, whereas the three species *biflexa*, *hollandia*, and *wolbachia* belong to the saprophytic, 'nonpathogenic' group. In addition, there are at least four species not yet formally named (Brenner et al. 1999). The choice of the names 'interrogans' and 'biflexa' for species of leptospires was unfortunate and their use for both the former serologically defined species and the current genetically determined species is confusing. The few recent comprehensive reviews of the nature and significance of the members of the genus *Leptospira* include those of Adler and Faine (2002), Faine et al. (1999), Levett (2001), Torten and Marshall (1994), and Weyant et al. (1999).

INTRODUCTION AND BRIEF HISTORICAL PERSPECTIVE

Introduction and general perspective

Pathogenic leptospires are important primarily for their ability to cause disease in humans and animals. Nonpathogenic leptospires need to be differentiated from pathogens to avoid confusion in diagnosis and epidemiology. Scientifically, the leptospires are intrinsically important because they are phylogenetically an ancient group of bacteria, unique in their structure, metabolism, and some of their genetic mechanisms.

Leptospirosis is a potentially fatal disease of humans or animals caused by one of the pathogenic leptospires. It is prevalent globally as an acute febrile, sometimes congenital or chronic infection of wild or domesticated animals, mainly mammals and marsupials. Chronically infected animals are survivors of an initial acute infection. Leptospires persist in the renal tubules of kidneys in carrier animals, whence they are excreted in urine into the environment to contaminate water and soil, leading to infection of further animals of the same or different species. In some domestic animals genital carriage and sexual transmission are important. Humans are infected incidentally, affected by an acute febrile, sometimes fatal, clinical illness. Sometimes the disease is subclinical. Humans do not usually become chronic carriers or transmit infection to other humans or animals. Economic loss occurs through animal disease and mortality, loss of productivity, and illness or death in humans. There is a significant social cost of the disease both in humans and animals. Immunity to reinfection with the same serovar or closely related serovars follows infection. Significant topics for microbiological study of leptospires related to the control of leptospirosis include rapid diagnosis, mechanisms of attachment to and persistence in or on tissue cells in chronic carrier infection, and the identity and regulation of antigens important for immunity.

History of the leptospires

The history of leptospires and leptospirosis was reviewed extensively by Faine et al. (1999). Leptospirosis was described as a characteristic febrile jaundice of humans (Weil's disease) during the latter part of the nineteenth century. Its contagious nature and microbial origin were proved independently first in Japan by Inada and colleagues ('*Spirochaeta icterohaemorrhagiae*') in 1915 and soon after in Germany ('*Spirochaeta icterogenes*') by Uhlenhuth and Fromme; both groups isolated, cultivated, and described pathogenic leptospires. Leptospires had been seen, but not cultured, and named *Spirocheta interrogans* by Stimson as early as 1907, in silver stained preparations of liver from a patient believed to have died of yellow fever, whose viral origins were then unrecognized. The patient really had Weil's disease. Later, a saprophytic leptospira found in fresh water was described in 1914 and named *Spirocheta biflexa* but it was not cultivated. Noguchi proposed the name 'leptospira' ('thin spirals') in 1918 following detailed microscopic and cultural observations, believing it to be the cause of yellow fever. Controversy about the role of leptospires in yellow fever persisted until the yellow fever virus was identified and incriminated unequivocally. Microscopically and culturally identical, but antigenically different, leptospires were at first regarded and named as separate species, but later included as serotypes or serovars of a single genus, *L. interrogans*. In the 15 years or so from discovery until the 1930s, many of the important serovars prevalent throughout the world, and their host sources, were discovered (Kmety and Dikken 1993).

Most of the research on leptospires in the next two decades related to the discovery of new serovars, some of them responsible for milder anicteric types of leptospirosis. The low yields from the culture media containing 10 percent rabbit serum were significant impediments to serious research on leptospires as bacteria. There was little progress and much frustration in attempts to understand nutrition or the composition of antigenic fractions, compared with knowledge of other bacteria. Electron microscopy revealed much of the detail of structure during the 1960s and 1970s. The analysis of antigens did not escape from the net of serological classification until Yanagawa and Faine (1966) showed that leptospires were analogous to other bacteria in structure, and that characteristic antigens were

associated with structural elements. A full account history of research in leptospirosis is recounted in Faine et al. (1999)

In the USA, widespread leptospirosis of cattle and pigs due to '*L. pomona*' stimulated significant research into nutrition and cultivation of leptospires, much of it emanating from the laboratory of J.B. Wilson in Wisconsin during the 1960s, and from his former students thereafter. The most important single advance was probably the discovery that the only carbon and energy sources were the long-chain fatty acids essential for growth. They were toxic and had to be presented in a nontoxic form, detoxified by serum or serum albumin or another detoxicant in the medium. Bovine albumin oleic acid culture media improved yields up to 100 times those in rabbit serum medium, especially with aeration, and also allowed the isolation of some strains unable to grow in rabbit serum media. A profusion of isolates of many previously unknown serovars of leptospires necessitated correct identification for diagnosis, prognosis, and epidemiology, and for the development of vaccines. Consequently, leptospirosis researchers developed a preoccupation with serological classification, based only on absorption and cross-agglutination of antisera (Abdussalam et al. 1972). 'Factor analysis' (Kmety 1967) using batteries of absorbed sera to simplify identification was seldom used as it appeared to be more complex than the standard methods. ELISA methods were developed to analyze nonagglutinating as well as agglutinating antigens (Adler et al. 1980) and applied with monoclonal antibodies to identify epitopes involved in immunity, or useful for classification (Adler and Faine 1983; Kolk et al. 1984). For many years leptospires were classified in either the nonpathogenic group as '*L. biflexa*' or the pathogenic group as '*L. interrogans*', the latter term adapted from Stimson's description with the purpose of indicating doubt about the ultimate classification. The current system of genetic classification was adopted in 1994 (Abdussalam et al. 1965, 1972; Ellis 1995).

Much of the work on leptospires and leptospirosis has been supported or stimulated not by physicians or microbiologists but by veterinary public health sources and veterinarians, because the economic consequences of leptospirosis are loss of animal productivity and human food supplies, as well as zoonotic risks to humans. Historically, important developments in the last 20 years dealt with in the text below include: the lipopolysaccharide (LPS) and the LPS derivation of the antigens involved in immunity, and some of the partly characterized epitopes; cloned genes coding for outer membrane and other important proteins; genetic studies of special features of the leptospiral genome. Molecular techniques for identification have allowed genetic speciation on firm grounds and polymerase chain reaction (PCR) methods have been developed for identification and diagnosis.

HABITAT

Leptospires are motile aquatic bacteria whose natural habitat is surface waters, soil, and mud. They feed by attachment to surfaces where long-chain fatty acids are available (Kefford and Marshall 1984). A halophilic leptospire has been isolated from estuarine waters. Leptospires do not survive drying under usual conditions, but lyophilization can preserve them. Pathogenic leptospires enter their hosts through the integument in moist conditions. In the host they circulate and grow in an aqueous milieu and may attach to renal tubular cells in carrier animals, passing in urine into surface waters. Pathogenic leptospires adapt to environmental conditions including the salinity and temperatures of febrile mammals, renal tubular and bladder urine, and soil and surface water. Both pathogens and nonpathogens have been isolated from fast-flowing rivers and still surface ponds. Soil and subsoil type and structure are important for survival in dry periods (reviewed by Faine et al. 1999).

MORPHOLOGY AND VISUALIZATION

Leptospires are helical gram-negative bacteria, so thin that they are hard to see when fixed and stained by conventional bacteriological stains. Their characteristic shape is largely destroyed by heat fixation. Strong stains (carbol fuchsin) and stains that build up on the surface (flagellar stains, Giemsa, silver stains, immunostains) make them appear thicker and improve visualization. Electron microscopy reveals details of morphology. Phase contrast of live cultures is of limited value because the leptospires move rapidly out of phase. The routine method of observation is dark field microscopy of wet preparations. Leptospires pass through bacteriological filters of average pore diameter 0.2 μm.

Shape and structure

The leptospiral cell (Figure 1) is about 10–20 μm long. It comprises a peptidoglycan complex loosely

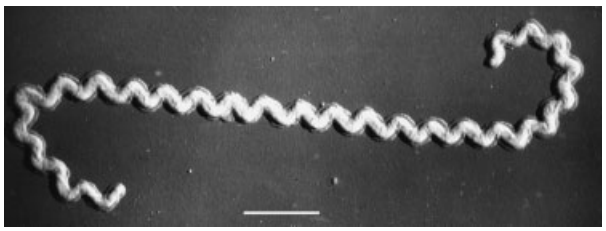

Figure 1 *Shadowed electron micrograph of a typical leptospire (*L. interrogans *serovar* Copenhageni*). The flagella run in grooves in the wall of the helical cylinder from a subterminal insertion near either end. The helical cylinder is surrounded by an outer envelope. Initial magnification ×40 000. Bar = 1.0 μm. (Original electron micrograph by Dr A. Chang)*

referred to as cell wall arranged as a flexible hollow tubular right-handed helix, containing cytoplasmic and genetic material. The amplitude of the coil is about 0.10–0.15 μm and its wavelength is about 0.5 μm. *Leptonema* is generally longer (13–15 μm) than *Leptospira* and has a longer average amplitude of 0.13 μm and wavelength of 0.6 μm; the cells thus appear wider microscopically. By contrast, *Turneria* is shorter (3.5–7.5 μm long) and more tightly coiled (wavelength 0.3–0.36 μm and amplitude 0.13–0.14 μm). Subterminally at either end of the helix a flagellum, essentially similar in structure and function to other bacterial flagella, is inserted in the cell wall and penetrates to the outer aspect of the helix, where it runs through the interior of the coil in a groove to end at about the middle of the leptospire. The two flagella seldom overlap. The flagellar origin appears as a visible bulge below the surface in shadowed electron micrographs. The whole is surrounded by an outer membrane, separated from the cell by a periplasmic space. In stained cross-sections in electron micrographs, the concentric layers are, from the outside, the outer membrane, the periplasmic space, the peptidoglycan, the inner membrane, and the cytoplasmic contents. The flagellum, when included in the plane of the section, is a darkly staining round structure lying in an indentation of the cell wall. Negative stained electron micrographs have revealed more of structure than have shadowed preparations. Cultural conditions and technical procedures affect the appearances of the leptospiral surface on electron microscopy; washing removes much of the outer membrane. There is an unusually high lipid content in leptospires, located mainly in the cell wall or outer membrane. When treated with various detergents or lysozyme the cell relaxes its helical shape and sheds its outer envelope. Gradually, more of the surface layers dissolve as the helix finally flattens in an empty flaccid sac, liberating detectable antigens in the process (Yanagawa and Faine 1966).

SPHEROPLASTS (LEPTOSPIRAL GRANULES)

In some cultures leptospires appear in a 'granular' form. The granules are small cystic structures, about 1.5–2.0 μm in diameter, inside which coiled remnants of the leptospiral cell can be seen. Once thought to be a cystic stage of a life cycle, they are really spheroplasts whose formation can be induced with ethanol, detergents, sodium deoxycholate, high salt conditions, lysozyme or mild heat. They can also be observed in tissues and in phagocytes (Faine et al. 1964). The outer envelope surrounding the spheroplast granules may be removed from them with its antigens largely intact after plasmolysis of the leptospires. Some cultures tend to form spheroplasts spontaneously; these strains probably produce lipase that releases from the medium free, lytic fatty acids not adequately bound to a detoxicant (Figure 2).

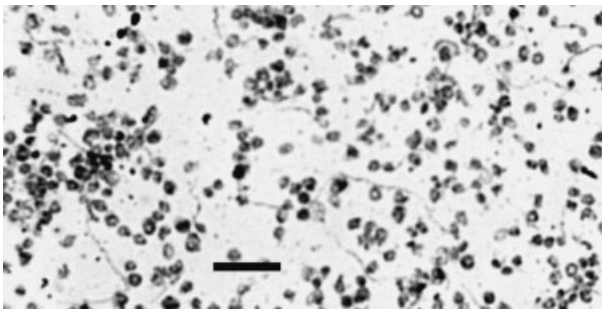

Figure 2 *Spheroplasts ('leptospiral granules') of* L. interrogans *serovar* Copenhageni *formed by heating a culture to 56°C. Thread-like degenerated leptospiral bodies can be seen towards the middle and the lower left corner. Stained with silver stain. Original magnification ×1 000. Bar = 15.0 μm. Adapted from (Faine et al. 1964)*

Flagella

Leptospiral flagella originate in a disc rotor and hooked proximal end structure in the cell wall, similar to other gram-negative bacteria. Flagella may be prepared for study by shearing them off leptospiral cells followed by differential or gradient centrifugation. In such preparations the flagella are seen as tight flat coils. The isolated flagellum is composed of a helically wound central core of proteins, surrounded by an outer sheath. The hook end is usually free of the rotor but may be contaminated with a bleb of lipopolysaccharide at its proximal end. There are associated flagellar antigens. Seven different flagellar proteins have been recognized. There is a 34 kDa protein associated with the core, of 11.3 nm, and a 36 kDa protein associated with the sheath, measuring 21.5 nm. A gene for an endoflagellar subunit protein, *flaB*, was cloned from *L. borgpetersenii* serovar Hardjo, expressed in *Escherichia coli* as a 32 kDa FlaB protein similar in sequence to FlaB proteins described in *Treponema pallidum* (Kelson et al. 1988; Mitchison et al. 1991; Trueba et al. 1992) The FlaB protein structure and its gene sequences are highly conserved throughout the species; a recombinant protein cross-reacted between serovars in immunoblots (Woodward and Redstone 1994). Characteristic flagellar antigen(s) associated with the flagellar sheath (Chang et al. 1974) were subsequently identified as the FlaA protein, which affects flagellar helicity in *Brachyspira* (Li et al. 2000a) and probably in *Leptospira*.

Microscopic appearances

When seen by direct dark field microscopy of wet preparations under optimum conditions, leptospires appear as a series of bright dots arranged in a flexible chain. Typically they are translationally motile and spin fast but spasmodically on their long axes; the loose hooked end looks like a hollow bulb. Occasionally

leptospires bend suddenly along their length in a jerky movement. There are also straight mutant forms, whose flagella are inserted closer to the ends of the cells and which are much less translationally motile, but spin as well as the hooked variety (Figure 3).

It is convenient to observe cultures microscopically in flat drops on a very clean thin slide, without a cover-glass, using a low power, long working distance objective and a low-power dark field condenser of low numerical aperture. For detailed observation of leptospires, a very clean thin slide is required; a drop of the fluid for examination is placed on it and covered with a thin, very clean cover-glass. Any dirt or grease or smear will cause diffraction of light and destroy the contrast required for the darkfield illumination. It is useful but not necessary to seal the edges of the cover-glass to prevent movement in the preparation through convection and evaporation at the edges. The slide is sealed to the surface of an oil immersion darkfield condenser with nonrefracting microscope immersion oil to prevent loss of light by diffraction at air–glass interfaces. An oil immersion objective fitted with a central stop, or a diaphragm to reduce the numerical aperture below that of the condenser is required. Centering of the light path and focusing the condenser are critical for successful observations. After locating the field under low power using dry objectives, a drop of immersion oil is placed on the cover-glass and the oil immersion objective used to focus on the leptospires in the field. Faine et al. (1999) described the technical procedures in detail.

Motility

Leptospires are motile bacteria; generally an immobile leptospire is dead. The characteristic motility of leptospires results from the rotation of the flagellum, generating a helical wave that propels the helical cell in the opposite direction. The precise mechanisms by which flagella generate motion may well vary in different spirochetes (Li et al. 2000b). A mutant of *L. biflexa* lacking flagella retained its helical shape and viability (Picardeau et al. 2001). In fluid media, leptospires can travel about 7–10 μm in a second. In viscous fluid media the speed of movement is increased in proportion to the viscosity. Leptospires are attracted to more viscous environments by 'viscotaxis'.

Recently isolated leptospires growing in media containing blood or serum appear to move faster than laboratory strains, possibly because of the viscosity of the medium. In semisolid agar, in which there are microscopically invisible particles, or in tissues, leptospires can become completely flexible throughout their length and wind through the interstices of the medium in either direction. They resume a rigid conformation and rapid spinning and translational movements as soon as they reach the fluid medium; part of the leptospira can be rigid and rotating while the other end is flexed around particles.

CULTURAL CHARACTERISTICS AND GROWTH REQUIREMENTS

Leptospires are grown routinely in liquid media, occasionally slightly thickened with 0.1–0.2 percent agar. Generally an inoculum of 1–10 percent of the volume of fresh medium is transferred by pipette. Working with liquid media demands the utmost care in their sterilization and quality control and in aseptic techniques, to prevent contamination by extraneous air-borne or filterable water-borne microorganisms, including other leptospires. Colonial growth in solidified media in plates or tubes is primarily employed for research.

Cell division

The stages in division in leptospires can be reconstructed from electron micrographs and direct observation. First, the cell wall constricts about the middle of the length,

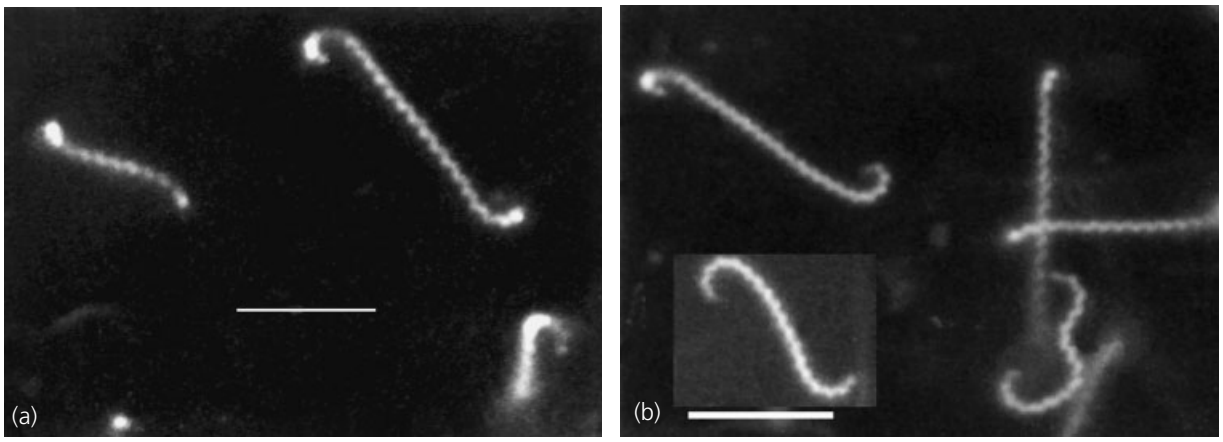

Figure 3 *Typical leptospires (*L. interrogans *serovar* Copenhageni*) seen by high-power dark field microscopy. Initial magnification ×1 000. Original photomicrographs by Drs T. Vinh and S. Faine. Bar = 5.0 μm. Adapted in part from Faine et al. (1999)*

beneath an otherwise intact outer membrane, resulting in fusion of the closed ends to form two new ends, one for each of the new cells. Near the constriction, a new flagellar origin appears from which a flagellum grows towards the middle of the newly formed cell. Last, the outer membrane constricts and pinches off a discrete new cell. About the time of division, the leptospire becomes hyperflexible at the site of future separation; it may bend sharply on itself, while retaining its motility, until the two new cells separate. In media deficient in amount or balance of long-chain fatty acids, leptospires may elongate extremely, or fail to divide (forming long chains), or both. Clearly the nutritional needs for growth (elongation) and division are different. Nothing is known about metabolic or molecular events in cell division specific for leptospires.

Optimum conditions: temperature, pH, osmolarity, and other conditions

TEMPERATURE

Both pathogens and saprophytes grow in the laboratory in an optimum temperature range of 28–30°C, with extremes of 11–42°C. Growth at 11–13°C has been proposed as a phenotypic test for *L. biflexa*. Pathogens grow in mammalian hosts at febrile body temperatures, and in chick embryos and young chicks around 40–42°C, but do not grow well in laboratory media at these temperatures unless they are adapted. In response to a change in temperature, leptospires upregulate the expression of a range of proteins, including homologs of common heat shock proteins in other bacterial species (Ballard et al. 1993, 1998; Nally et al. 2001a, b; Stamm et al. 1991).

pH

Leptospires die in acid conditions at pH below about 6.5, but tolerate more alkaline conditions up to about pH 8.4. Cultures will grow in the range pH 7.2–7.6.

OSMOLARITY

Most of the culture media for leptospires contain a final molarity of salts of about 0.05 M, about one-third of the concentration in other bacteriological media. Pathogens can grow in laboratory media at salt concentrations of 0.85 percent NaCl at 37°C but avirulent pathogens and nonpathogens cannot do so above 30°C (Faine 1959). Halophilic leptospires require sodium ion concentrations of 0.22–0.44 M for growth and can tolerate concentrations up to 0.65–0.75 M (Cinco et al. 1975).

OXIDATION–REDUCTION POTENTIAL

Leptospires are aerobic bacteria that do not tolerate reducing conditions or anaerobiosis, when the oxidation–reduction potential is less than about *E*h - 0.250 mV at pH 7.2.

Growth

Leptospira strains grow slowly, compared with most common pathogenic bacteria; colonies can take from 3–7 days to 3 weeks to appear. Some strains may not grow at all on solid media. The slow growth rate in solid media limits the use of plate counts to measure viability and impedes the rate of progress in molecular studies.

Leptospires grow in still cultures of liquid media at 30°C with a doubling time of 6–8 h under optimum conditions. A 10-fold increase in numbers can be achieved in 24 h. Aeration or agitation increases the yield. Maximum growth can be expected in 3–10 days, depending on the strain and the medium. Maximum growth densities are about 5×10^9–10^{10} leptospires per ml, with best conditions and aeration; cultures are then visually turbid but measurable turbidity is relatively low. *Leptonema* grows rapidly in trypticase–soy broth (TSB) medium to reach maximum density on incubation for 18–72 h at 30°C. The fatty acid concentration is the limiting factor for continuation of growth in cultures of *Leptospira*. Supplementary Tween added to cultures that have exhausted all their available fatty acids will considerably increase the final density. Some cultures die rapidly after the end of the logarithmic phase, because lipases from autolysing leptospires liberate lytic free fatty acids. The doubling time for growth in the intact animal body in experimental infections was 6–8 h.

Growth is measured in liquid media by either direct counts or turbidity. The best way to count leptospires is to use a bacterial counting chamber, or to count them in a measured volume placed under a standard size coverglass, using a calibrated eyepiece graticule micrometer. The culture must be diluted accurately if it is too dense. Motile leptospires are counted as viable; nonmotile and obviously dead and degenerate leptospires are not counted. Motility is seldom so fast that it creates a problem. The usual conventions for counting in counting chambers are observed in relation to leptospires on or overlapping lines (Faine et al. 1999). Leptospiral cultures are much less turbid than those of other bacteria at peak growth. Turbidity measurements are limited in value to estimating the total count, irrespective of viable numbers, in heavily growing cultures at the end of their logarithmic phase, at densities above about 10^8 leptospires per ml, when growth is just easily visible by eye. Nephelometry is more sensitive but limited to cultures denser than 5×10^7 leptospires per ml.

Growth requirements

ATMOSPHERIC CONDITIONS; O_2, CO_2 AND AERATION

Leptospires require an oxygen source, but a measured lower limit of oxygen concentration seems not to have been established. It is assumed that animal tissues in

which leptospires grow and apparently flourish are lower in oxygen than culture media, especially in the presence of inflammation, hemorrhage, cellular damage, and autolysis, and tissue disorganization during the acute stages of infection. Aeration of cultures by sparging or shaking increases growth, although it can cause problems with frothing in protein-rich media. CO_2 is essential, but the limiting amounts are not known.

CARBON SOURCES

Pathogenic leptospires will not grow without long-chain ($C_{12–18}$) unsaturated fatty acids, in whose presence some strains can also utilize saturated fatty acids. *Leptospira biflexa* strains can grow on long- or short-chain, saturated or unsaturated fatty acids. Some pathogens may start to grow sooner from small inocula, especially on solid media, if pyruvate, pyruvate and CO_2, or glycerol are added to the medium (see section on Growth characteristics below). Knowledge of nutritional requirements comes mainly from studies on relatively few isolates made at a time when it seemed that information relevant to any leptospire could be extrapolated to all. Differences in nutrition and metabolism between leptospires may be related more to species than to serovar.

The form of presentation of the fatty acids is important because they are potentially toxic to the leptospires, lysing the cells by destroying the integrity of the outer membrane. Nontoxic 'Tweens', used widely in media as sources of fatty acids, are commercially available sorbitan monoesters of fatty acids; Tween 80 contains oleate, Tween 60 stearate, and Tween 40 palmitate. Their crude industrial form may need to be purified of contaminating free fatty acids and degradation products before use in media. The choice of the chain lengths of the fatty acids and their relative concentrations depends on the strains to be cultivated. In addition, a detoxicant such as bovine serum albumin (BSA), in a final concentration of 1.0 percent, is used to absorb and release fatty acids slowly. BSA may also itself be contaminated with free fatty acids and may need to be purified for use. Likewise, agar used in media may contain contaminating fatty acids which must be removed before use. *Leptonema* will grow without added fatty acids in TSB medium.

NITROGEN SOURCES, PURINES, AND PYRIMIDINES

The only essential nitrogen source is ammonia. Some strains metabolize amino acids, probably producing ammonia by deamination. Urease, inhibited by ammonia, has been described. All *L. biflexa* and other nonpathogens and *Leptonema* can synthesize their own purines and pyrimidines. *Turneria parva* requires purines. In general, all *L. borgpetersenii* and *L. santarosai* and some strains of *L. interrogans* synthesize purines, whereas all the pathogen group require pyrimidines.

OTHER REQUIREMENTS FOR GROWTH

Phosphates, sulfates, ferric iron or hemoglobin (or heme), calcium and magnesium, thiamine and cyanocobalamin are essential. Traces of copper and manganese are also required; these are included in the recipes for oleic–albumin based media, while in serum media they are provided from tap water, serum or other ingredients.

Growth characteristics and appearances of cultures

IN LIQUID MEDIA

Cultures of leptospires in liquid media appear visually clear until densities of about 10^7 per ml are reached. The first appearance of growth is a birefringence on swirling the culture vessel, best seen with oblique lighting against a dark background. Maximum turbidity, well below that achieved by larger bacteria, is reached after about 3–20 days of incubation, depending on the inoculum size, the strain and its adaptation to the medium and conditions, and the growth phase at the time of subculture. There may be a long lag of several days before freshly isolated strains begin to grow. Some cultures autoagglutinate; clumps of actively motile tangled leptospires sink to the bottom of the vessel. Otherwise, leptospires do not settle during cultivation, but precipitates of insoluble salts, fatty acids or amino acids can occur and be a nuisance. Removal of leptospires from cultures for preparation of antigens or for other laboratory manipulations requires a centrifugal force of about 10 000 $\times$ *g* for 15–20 min.

IN SEMISOLID MEDIA

When growing in tubes of media containing agar (0.1 percent or more) after surface or stab inoculation, the distribution of leptospires is restricted mainly to one or more disks 0.1–0.5 mm thick that appear 0.1–5.0 mm below the surface of the medium, although leptospires will often be detected below the disks.

The disks, known as Dinger's disks, represent colonial growth accumulated at a level of optimum oxygenation. If one of the redox indicators 1-naphthol-2-sodium sulphonate indo-2,6-dichlorophenol (*E*h – 0.180 mV at pH 7.2) or 2-6-dichlorophenol-indophenol (*E*h – 0.200 mV at pH 7.2) is incorporated in the medium at a concentration of 1 in 100 000, the blue color of the medium when inoculated discolors around the areas where growth begins, usually at the level where the disks will appear later. Where growth occurs only in disks, the medium gradually decolorizes or changes color from the bottom of the tube upwards as oxygen is absorbed, until the zone below the disks is pale yellow or pink. The medium above the disks remains blue. If single colonies develop in the depths of the medium, the dye fades and becomes pale yellow or pink at the place in the tube

where the gray spherical colonies will later appear. Both disks and colonies may develop in the same tube.

IN AND ON SOLID MEDIA

Leptospires are usually grown on solid media only for research because growth is too slow to be useful for routine diagnosis. Some isolates grow on the surface of media containing 1.5–2.0 percent agar in petri dishes. The agar must not be too stiff for the leptospires to move through it easily and the plates must be sealed or otherwise protected from drying during incubation. Inoculation of a drop with a spreader or by flooding is better than scratching the agar surface when streaking it with a wire loop. Surface colonies are transparent, often very flat, small (less than 2 mm in diameter), and irregular. In less solid media containing 0.8–1 percent agar, growth occurs below the surface, first visible after 3–10 days as a pinpoint hemispherical colony that spreads centrifugally. Colony appearances depend on the density and depth of the agar and the motility of the leptospires. Straight leptospires, not very translationally motile, form small dense gray spherical subsurface colonies (small, opaque, defined border or 'SOD') that do not spread and reach a diameter of 1–3 mm. Leptospires that are conventionally translationally motile may form a larger, fluffy colony (sometimes called hazy growth, or a large, opaque, hazy edge or 'LOH') that may spread rapidly to form a gray ring with a sharply defined edge ('LOD'); this ring may grow wider to occupy a large part of the agar. In a thin layer of medium (2–3 mm) the colony soon looks like a ring of gray with a transparent center and sloping sides, because the medium is not deep enough for continued hemispherical growth. Details are described by Faine et al. (1999). The gray edge indicates a mass of actively motile leptospires; few leptospires, most of them nonviable, will be found internal to the edges of the ring. Incubation to detect growth should be continued for up to 3 weeks. More than one colony type can occur on the same plate. If redox dyes are added to the medium as described above, the color in the medium fades at the points where colonies will appear, forecasting the initiation of colonial growth. A subculture may be taken carefully with a pipette from the spreading edge of the colony. Contaminated cultures or environmental specimens inoculated as a discrete drop on the surface at the centre of the plate can be purified by subculturing leptospires from the edge of the ring of growth.

Culture media

Almost invariably, media contain heat-labile proteins or other ingredients and are sterilized by filtration. Either rabbit or other animal serum, or BSA forms the basis of current culture media. Yields are higher and growth faster in oleate–albumin media. Media free of protein are preferable and available for vaccines and certain other purposes; it is impossible to wash away the last traces of proteins from the culture medium adhering to the leptospiral surface. Liquid media are used for the maintenance of stock cultures and the propagation of cultures used to prepare vaccines and antigens for serological tests.

TECHNICAL NOTES, FORMULATIONS, AND PREPARATION OF MEDIA

Generally, leptospires are grown in tubes of flasks at 28–30°C. The depth of medium in unshaken tubes or flasks should be less than 5 cm; shaking, agitation or sparging with air or oxygen plus CO_2 (with care to minimize frothing) will maximize the yield and growth rate. Cultures should be checked for growth or contamination after 3–4 days and subcultured after 7–21 days; however, leptospires will survive in sealed tubes of medium at room temperature (ideally 20°C, certainly below 40°C) for months or years.

Oleic acid–albumin (OA) media and serum media

Details of composition and preparation of media are found in Alexander (1991) and Faine et al. (1999). All media are hypotonic with respect to mammalian physiological conditions. The most widely used OA medium is EMJH (Ellinghausen, McCullough, Johnson, Harris), based on 1 percent BSA and Tween 80. A BSA stock solution containing other mineral and heat-labile ingredients that should not be autoclaved is sterilized by filtration and added to an autoclaved phosphate-buffered basal medium. Most serum media use a phosphate-buffered base containing a small amount of bacteriological peptone; 10 percent rabbit serum to supply both albumin and fatty acids; and essential supplements such as thiamine, cyanocobalamin, and iron in the form of hemoglobin from lysed erythrocytes. The medium should be just pink and pH 7.2–7.4. It is usually sterilized by final filtration of all the ingredients. A common formulation is Korthof's medium. Nonpathogenic leptospires are generally grown in the same media as pathogens, although *Leptonema* grows well and rapidly in TSB medium.

Special selective and indicator media

Special media were developed empirically to isolate fastidious leptospires, especially *Leptospira interrogans* serovar Bratislava, from pigs and other animals (Adler et al. 1986; Ellis et al. 1985). Composition of media and conditions of cultivation must be adjusted to special needs. Selective media containing one or more of cycloheximide (100 μg/ml), bacitracin (40 μg/ml), 5-fluorouracil (50–1000 μg/ml), nalidixic acid (50 μg/ml), polymyxin-B sulphate (5 units/ml), polymyxin B (2 μg/ml), rifampin (10 μg/ml) or vancomycin (10 μg/ml) have been

recommended to reduce contamination on primary isolation or to purify contaminated cultures. They should not be used routinely as a substitute for careful technique. Subcultures must be made within 4 days.

Protein-free and low-protein media

Media with little or no protein were developed for vaccine production, rather than for nutritional studies. Utmost care is required to minimize toxicity from unwanted fatty acids. Chemical methods or solvents are used to 'clean' Tweens and the specially selected charcoal used as an adsorbent of fatty acids in place of protein. Some of the media used for vaccines are subject to commercial secrecy or patent and have not been published. In order to grow successfully in a protein-free medium, leptospires must first be adapted to it and then subcultured regularly and frequently.

Solid and semisolid medium

Almost any medium may be solidified by the addition of 0.5–1.0 percent agar to allow subsurface colonial growth, or 2 percent agar for surface growth. Growth in and on solid media is described above.

QUALITY CONTROL

It is essential to check the ingredients for culture media for quality before use. BSA is very hygroscopic; it should be kept and used dry, or a correction made for the weight of the water content. Each batch must be tested or previously certified suitable for the growth of leptospires. Some batches can be improved by fat extraction. All chemicals should be analytical grade. Agar should also be tested for freedom from toxic fatty acids. The quality of the water used for protein-free media is critical. The vessels used for preparing media should be dry; water used for solutions must be sterilized to prevent filter-passing leptospires in the water from contaminating the media. After preparation, the media must be checked for sterility by incubation for 3–4 days at 28–30°C as well as at 37°C. The possibility of contamination by leptospires should not be overlooked. The utmost care in labeling during subculture is essential because there are no obvious features to distinguish one leptospire from another. Records of origin of an isolate, its identification and its subculture history are essential. Serological identity should be checked, confirmed, and recorded periodically by agglutination to titer with a reference antiserum. Genetic identity should also be checked periodically where this is appropriate.

METABOLISM

Knowledge of leptospiral metabolism depends largely on studies reported before genetic speciation was known. It may be fallacious to deduce from them that all species of leptospires are metabolically identical. All leptospires are aerobic or microaerophilic chemo-organotrophs and use O_2 as a final electron receptor via cytochromes. Catalase, cytochromes *a*, *c*, and c_1 and oxidases have been identified. Essential long-chain fatty acids, longer than C_{15}, are degraded by β-oxidation for energy. Acid production from sugar fermentation does not occur, but key enzymes in carbohydrate metabolic pathways are present. Sero-specificity depends on the presence of small carbohydrates and their arrangement in the LPS (see the section on Serological groups below). Leptospires cannot synthesize long-chain fatty acids from pyruvate or acetate, but they can shorten long chains; the cellular lipid composition partly reflects the fatty acid composition of the medium. A characteristic component of leptospires, *cis*-11-hexadecenoic acid, is rare in other bacteria. Positionally specific trioleinase lipases are found in all *L. biflexa* and some pathogens, but not in *L. borgpetersenii*, some *L. interrogans*, *L. noguchii*, *L. santarosai*, and *L. weilii*. Hemolytic phospholipases including sphingomyelinase C exist in some pathogens, while *L. biflexa* contains phospholipase A_1 and lysolecithinase. Hemolytic activities dependent on phospholipases are specific for the erythrocytes of the animal concerned, determined by the composition of the dominant phospholipids in its cell membranes. Fatty acid esterases are ubiquitous among leptospires. The genetics and distribution of sphingomyelinase genes have been studied and reviewed (Segers et al. 1992; Segers 1991).

Ammonia is the essential source of nitrogen. In serum media it may be obtained by deamination of amino acids, particularly asparagine. In other media it is provided as ammonium salts. What little there is known about amino acid metabolism is unremarkable except that isoleucine synthesis may follow either the conventional threonine pathway, or an unusual pyruvate pathway, or both; genes for regulating steps in the latter have been identified. A urease, inhibited by ammonia, and various aminopeptidases have been described. Not all leptospires require purines or pyrimidines. Purine metabolism is mentioned below. Methionine biosynthesis in *L. meyeri*, controlled by the *metY* gene, occurs through direct sulphydralation using O-acetylhomoserine as a substrate (Belfaiza et al. 1998).

MOLECULAR BIOLOGY OF *LEPTOSPIRA*

Slow leptospiral growth on solid media and slow, relative metabolic inertness in usual phenotypic tests for other bacteria mean there are few physiological or colonial markers and very few classical genetic studies. Mutants have been selected to grow in media containing either boiled, as opposed to fresh, serum; others grow in antiserum to the parent strain. There are no studies of the genetics of these mutations, or of straight variants, usually forming small colonies, that appear spontaneously in some strains. A straight variant of *Leptonema*

illini was produced using nitrosoguanidine. Virulence is lost on subculture in the laboratory but leptospires able to grow in vivo can be selected from the culture population by inoculating experimental animals. Plasmids and the mechanisms of genetic transfer strongly assumed to occur between leptospires are elusive. Transformation has not been reported among leptospires. It is not yet possible to introduce DNA into pathogenic leptospires artificially and deliberately. A bacteriophage for *L. biflexa* was described, but none has been found that affects any pathogen (Saint Girons et al. 1990, 2000; Saint Girons 1991).

The leptospiral genome and its elements

The chromosome of *Leptospira* is characterized by a G + C content of 35–41 mol%, depending on species, with a genome size originally estimated to be ca. 5 000 kb, measured in pulsed-field gel electrophoresis after digestion with *Not*I, *Nhe*I or *Apa*I (Baril and Saint-Girons 1990). Using mainly the restriction enzymes *Not*I and *Sfi*I, a physical and genetic map *L. interrogans* serovar Pomona was constructed (Zuerner 1991), predicting a genome size of ca. 4 750 kb, similar to that of serovar Icterohaemorrhagiae. The genome consists of two circular replicons, estimated to be approximately 4 750 kb and 350 kb in size (Boursaux-Eude et al. 1998). The complete genome sequences of two very closely related serovars, Lai and Copenhageni, of *L. interrogans*, have been published recently (Nascimento et al. 2004; Ren et al. 2003), revealing almost identical genomes. The large and small replicons comprise 4 330 and 358 kb, respectively. The genomes of two strains of *L. borgpetersenii* serovar Hardjobovis (unpublished) are slightly smaller, with chromosome sizes of 3 614 and 317 kb. The smaller replicon is considered a chromosome because of the presence of essential genes on it. Interspecies comparison reveals regions of colinearity of up to 30 kb, but with large-scale chromosomal rearrangements. A comparison of genetic maps for strains of *L. interrogans* serovars Icterohaemorrhagiae and Pomona indicated considerable heterogeneity and variability within the species *L. interrogans*, that involves rearrangements of large segments of chromosome (Boursaux-Eude et al. 1998; Zuerner et al. 1993).

Both pathogenic and saprophytic leptospires contain two ribosomal 23S rRNA genes (Fukunaga and Mifuchi 1989b). Two genes for 23S rRNA and for 16S rRNA, but only one for 5S rRNA, were found in *L. interrogans* serovar Canicola, each located far from other RNA genes. There were two 5S rRNA genes in *L. biflexa* (Fukunaga and Mifuchi 1989a), one of which was sequenced (Fukunaga et al. 1992). Pathogenic strains of leptospires contained only one highly conserved 5S rRNA gene (Fukunaga et al. 1992). The 23S rRNA was further processed to 14S and 17S rRNA, in a pattern seldom found in prokaryotes, in *L. borgpetersenii* serovars Hardjo (subtype Hardjoprajitno) and Balcanica (Hsu et al. 1990). The two genes for 5S rRNA in *L. biflexa* strains were located several kb apart on the chromosome, with divergent flanking sequences (Fukunaga et al. 1992). Thus, in contrast to the situation in many other bacteria where the 16S (*rrs*), 23S (*rrl*) and 5S (*rrf*) rRNA genes are clustered and cotranscribed, those in *Leptospira* widely scattered on the large chromosome (Baril et al. 1992; Saint Girons et al. 1992).

Although no compound transposons have been found in the genus *Leptospira*, Zuerner (1994) identified and characterized IS*1533* from *L. borgpetersenii*. Genome sequencing has indicated at least 80 intact copies of IS*1533* on the genome. A PCR assay based on IS*1533* sequences was adapted for identification of *L. interrogans* (sensu lato) strains. A similar IS element was reported in serovar Tarassovi (GenBank X77623). An IS*3*-like element, designated IS*1500*, was present only in pathogenic leptospires (Boursaux-Eude et al. 1995). IS*1500* insertions were present only on the large chromosome and appeared to coincide with genomic regions which had undergone rearrangement. This element was also used as the basis for fingerprinting and epidemiological analysis of leptospiral isolates (Zuerner and Bolin 1997).

Interestingly, the serovar Hardjo (type Hardjobovis, but not Hardjoprajitno) LPS biosynthetic locus is bounded by two IS*1533* elements (de la Peña-Moctezuma et al. 1999; Kalambaheti et al. 1999). A second IS element was also found in an intergenic region of the Hardjobovis locus; it appeared to be intact and is related to the IS*5* family, but no functional studies were performed (Kalambaheti et al. 1999). Similarly, an apparently intact IS*1500* element was found to disrupt the *orf35* gene in Ictero No I, but not RGA, strains of serovar Icterohaemorrhagiae; this gene encodes a putative membrane protein within the LPS biosynthetic locus (de la Peña-Moctezuma et al. 2001). It has been speculated that the presence of these IS elements may regulate gene expression leading to differences in LPS structure, but there is no evidence yet for such a role.

The early branching of spirochetes before gram-positive and gram-negative bacteria (Woese 1987) is consistent with their heat shock regulatory mechanisms, which show characteristics of both gram-positive and negative bacteria. The *groE* and *dnaK* operons of *Leptospira* have been identified, cloned, and sequenced (Ballard et al. 1993, 1998; Stamm et al. 1991). The *groE* operon encoding the GroEL and GroES proteins exhibits features found in heat shock operons regulated by either $Sigma^{32}$ or CIRCE (controlling inverted repeat of chaperone expression) (Zeilstra-Ryalls et al. 1991; Zuber and Schumann 1994). These are generally found in gram-negative and gram-positive bacteria, respectively. The CIRCE element was also found upstream of the

dnaK locus, which contained the genes *hrcA*, *grpE*, *dnaK*, and *dnaJ* (Ballard et al. 1998). The genetic organization and regulation of this locus are thus more like those in gram-positive than gram-negative bacteria (Zeilstra-Ryalls et al. 1991; Zuber and Schumann 1994).

Genetic analysis of *Leptospira* has been impeded by the lack of genetic exchange systems. Early reports (Ritchie and Ellinghausen 1966) of bacteriophage-like particles in leptospires were not confirmed, but Saint Girons and her colleagues (1990) isolated three bacteriophages, whose replication was limited to the saprophyte *L. biflexa*. One of these phages, LE1, was shown to replicate as a plasmid in *L. biflexa* and was used as the basis for the first *L. biflexa-E. coli* plasmid shuttle vector, pGKLep4 (Saint Girons et al. 2000). No such system has yet been reported for the pathogenic leptospires. A restriction-modification system has been demonstrated, at least in *L. biflexa* (Brenot et al. 2001).

There are only two reports of gene inactivation by recombination-mediated allelic replacement in *Leptospira*. The kanamycin resistance gene from pGKLep4 was used to inactivate the *flaB* gene, encoding the flagellar subunit protein, in *L. biflexa* (Picardeau et al. 2001). Mutants were nonmotile and lacked flagella and hooked ends, but retained their helical shape. Inactivation of *recA* in *L. biflexa* resulted in reduced growth rate and altered nucleoid morphology (Tchamedeu Kameni et al. 2002). There are no published reports of allelic replacement in pathogenic leptospires.

THE LEPTOSPIRAL SURFACE

The leptospiral outer envelope (OE) generally resembles the outer membrane of gram-negative bacteria; it is also the site of most of the antigens known to be involved in immunity or diagnosis. The main difference is a high lipid content and a relatively low transmembrane outer-membrane protein content in leptospires (Figure 4).

Lipopolysaccharide

Leptospiral LPS comprises the major surface component of leptospires and is the target for agglutinating and opsonizing antibodies (Farrelly et al. 1987). As an agglutinating antigen, LPS is also important for serological classification of leptospires. The structure of LPS remains unknown. However, chemical analysis of leptospiral LPS showed the presence of common hexoses, amino hexoses, and pentoses, and some sugars found more rarely as LPS components, such as xylose and arabinose. The detection of keto-deoxy-octulonate (KDO) in the LPS of *L. interrogans* serovar Copenhageni and *L. borgpetersenii* serovar Hardjo is consistent with a composition similar to that of typical gram-negative LPS.

Genetic analysis has identified the *rfb* loci involved in the biosynthesis of the LPS O-antigen in several leptospiral serovars. The locus in serovar Hardjo contains at least 31 open reading frames (ORF) that encode enzymes involved in the biosynthesis of activated sugars, glycosyl transferases, and sugar processing and transport proteins (de la Peña-Moctezuma et al. 1999; Kalambaheti et al. 1999). Leptospiral LPS appears to be assembled via the classical Wzy (Rfc) dependent pathway. A comparison of the *rfb* loci of 14 other *L. interrogans* serovars revealed conservation at the 3′ end, but genes at the 5′ end vary among serovars, or show more genetic drift (de la Peña-Moctezuma et al. 2001). This region thus appears to encode biosynthetic enzymes and glycosyl transferases responsible for serovar specificity and some genes of unknown function.

Protein and lipoprotein antigens

OmpL1, the first leptospiral surface protein to be identified, is a transmembrane protein with porin activity which exists in a typical trimeric form in the leptospiral outer membrane (Haake et al. 1993; Shang et al. 1995), that contains lower concentrations of proteins than

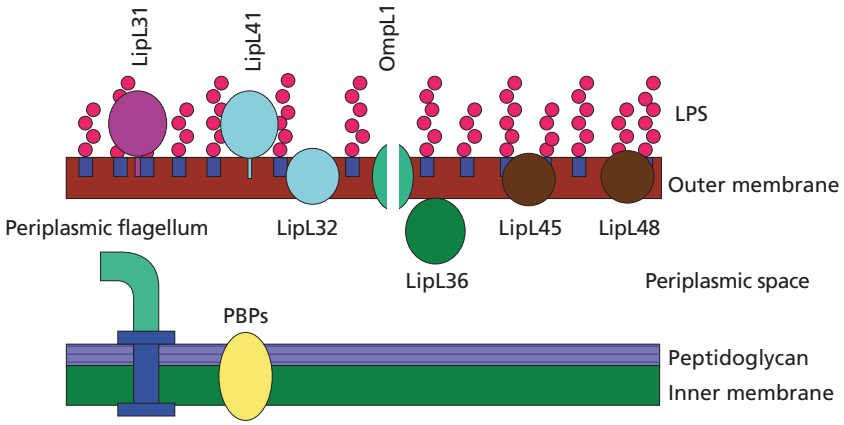

Figure 4 *Diagramatic representation of the leptospiral surface*

typical gram-negative outer membranes. However, the leptospiral outer membrane is abundant in lipoproteins, which are well conserved across the pathogenic species. One of these, LipL36 is not produced during infection, at least in the hamster kidney (Haake et al. 1998), although these results do not preclude a role for LipL36 at other stages of the infectious process. In contrast, the major OMP, LipL32, as well as OmpL1, LipL41, and LPS, are expressed during growth in the hamster kidney (Haake et al. 2000; Zuerner et al. 2000). LipL32 has been investigated as a potential serodiagnostic antigen (Flannery et al. 2001) and was shown to stimulate partial immunity in hamsters (Sonrier et al. 2000). LipL41 and OmpL1 when administered in combination, but not individually, were capable of eliciting an immune response which was partially protective in hamsters (Haake et al. 1999). Several other outer membrane lipoproteins have been identified (Cullen et al. 2002; Matsunaga et al. 2002), some of which show differential expression under a range of environmental conditions. Interestingly, the usual L-X-Y-C consensus sequence for transport and processing of gram-negative lipoproteins varies substantially amongst spirochete lipoproteins and the spirochetal lipobox sequence of L(A/S)-L(V/F/I)-I(V/G)-A(S/G)-C has been proposed (Haake 2000; Zuerner et al. 2000). The properties of leptospiral outer membrane proteins have been reviewed recently (Cullen et al. 2004).

BIOLOGICAL PROPERTIES OF LPS

Despite the structural, biochemical, and immunological similarity of leptospiral LPS to gram-negative bacterial LPS, it is at least 10-fold less toxic for animals or cells. Nevertheless, leptospiral LPS can activate macrophages and act as a B-cell mitogen (Isogai et al. 1990a, b). It has been proposed that the reduced toxic activity is a result of the absence of β-hydroxy-myristic acid. Activation and signaling within macrophages occurs via CD14 and TLR2, rather than via TLR4 as seen for the LPS of gram-negative bacteria (Werts et al. 2001). Notably, TLR2 is commonly used as a receptor for gram-positive bacteria and for other non-LPS components.

Other localized structures and components

A glycolipoprotein (GLP) with a high content of toxic lipids (palmitoleic and oleic acids) is cytotoxic and lethal for laboratory animals. Its cytotoxicity in tissue culture is obscured by the absorption of the toxic lipid into the albumin used in the culture media. Patients and animals produce antibodies to GLP, which can be located in the tissues in infections (Alves et al. 1992; Vinh et al. 1986). GLP acts through its constituent long chain fatty acids (Vinh et al. 1986), and inhibits Na^+, K^+ATPase (Younes-Ibrahim et al. 1997a). Peptidoglycan from leptospires was cytotoxic, inducing the release of TNFα from peripheral blood mononuclear cells (Cinco et al. 1993). Heat shock proteins were located below the surface (Stamm et al. 1991).

CLASSIFICATION

A microorganism with the shape, dimensions, and cultural characteristics of a leptospire is identified provisionally as a member of the Leptospiraceae. Cultural phenotypic characteristics (rapid growth in TSB medium) as well as electron microscopy characterize *Leptonema*. Other isolates look the same microscopically or in culture; they cannot be differentiated by simple biochemical and cultural tests. There are two overlapping systems for further classification, genetic species, and serological typing. Species is determined genetically by DNA homology, 16S rRNA gene sequencing or other molecular methods. Subspecies categories are determined serologically, by serovar, while genetic and serological subtypes are recognized within serovars (Ellis 1995).

Phylogenetic relationships

Spirochetes comprise a phylum of ancient bacteria whose members are very divergent from one another when classified by 16S rRNA relationships. The most deeply branching individual group in the phylum is the family Leptospiraceae; among them the first to branch off is *Leptonema* (Paster et al. 1984, 1991; Paster and Dewhirst 2000). *L. biflexa* and related saprophytes form a group distinct from the pathogenic leptospires, although there is considerable homogeneity between these by DNA homology (Paster et al. 1991). Within the group identified as the 'pathogenic' group (formerly the 'interrogans complex' or '*L. interrogans*' sensu lato), two main branches exist; one contains the species *kirschneri*, *interrogans*, and *noguchii*, the other the species *borgpetersenii*, *santarosai*, and *weilii*. *L. fainei* and *L. inadai* form a distinct group (Perolat et al. 1998). The 'nonpathogenic' group (formerly the 'biflexa complex', '*L. biflexa*' sensu lato) comprised six major branches in addition to *Leptonema* (Ramadass et al. 1990, 1992) (Figure 5).

Genetic classification and species

SPECIES

A species comprises those leptospires whose DNA is 70 percent related and whose related DNA sequences contain 5 percent or fewer unpaired bases (divergence) (Ellis 1995; Watt et al. 1990; Wayne et al. 1987). There are 12 named species, with further groups awaiting classification. Analyses by restriction length fragment polymorphism (RLFP), pulsed-field gel electrophoresis (PFGE) of chromosomal DNA, arbitrarily primed PCR (APPCR), mapped restriction site polymorphisms

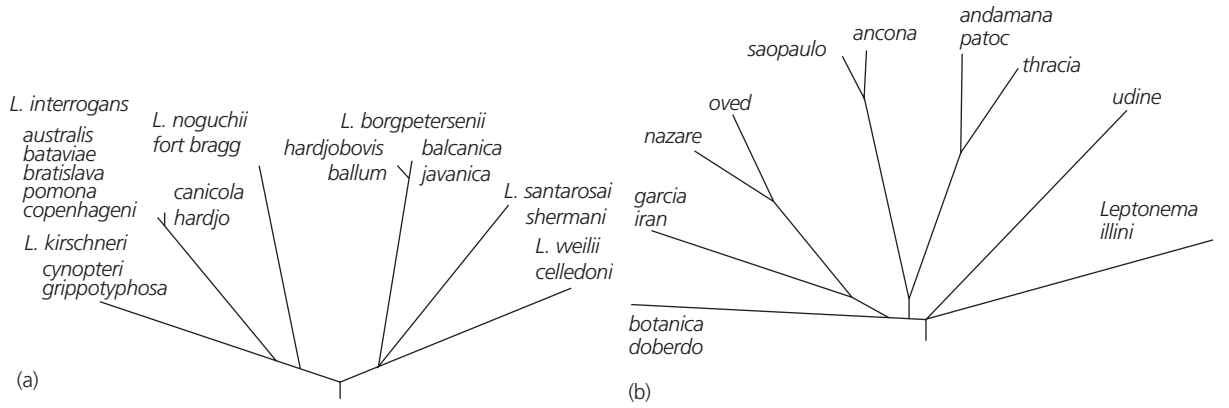

Figure 5 *Phylogenetic relationships of species of leptospires:* **(a)** *pathogenic varieties (adapted from Ramadass et al. (1992));* **(b)** *nonpathogenic varieties (adapted from Ramadass et al. (1990)). Information for the positions of* L. alexanderi *and* L. fainei *and other new species is not available.*

(MRSP), and random amplified polymorphic DNA fingerprinting (RAPD) are easier to perform and give similar results if calibrated (Gerritsen et al. 1995; Herrmann et al. 1992; Ralph et al. 1993). PFGE and RAPD fingerprinting can identify serovars uniquely in some cases. Serotyping identifies the same serovar antigens in more than one species. The recognized species, their G + C percentage ratios and some of the more common or important component serovars are listed with their serogroup identity in Table 1.

Serological groups

Leptospires were classified primarily by serology before the development of genetic methods. An arbitrary but useful definition of serovar was adopted many years ago, that two or more leptospires belong to the same serovar if a residual titer of 10 percent or less of the homologous titer of agglutinating antibodies remains in rabbit antisera after cross-absorption in standardized tests. About 255 serovars have been recorded among the Leptospiraceae. Serovars that are significantly different in their biological and pathogenic properties may be closely related at this 1 log difference level of titer. Some serovars exist in more than one species; that is, the same serovar-specific antigens can be expressed by members of more than one species. Serovars were designated in italic script until recently, when it became customary to use capitalized lower case letters.

The serological identity of an isolate depends on the dominance of one or more epitopes in a surface mosaic of LPS antigens, while the specificity of the epitope depends on its sugar composition and orientation (Ellis 1995; Kmety and Dikken 1993; Midwinter et al. 1994; Vinh et al. 1989). Monoclonal antibodies to LPS epitopes can identify isolates by generating a fingerprint based on agglutination profiles. Serovars that share common (serogroup-reactive) antigens and partially coagglutinate belong to serogroups. Serogroups have no taxonomic status but are useful for facilitating diagnosis and serological identification by antigens common to members of their group. Serological identification is clinically and epidemiologically significant but slow, painstaking, and labor-intensive.

Other phenotypic typing methods

Few phenotypic properties are available for classification. Colonial growth characteristics have not been used. Growth in TSB identifies *Leptonema*. Growth at 13°C (but not at 37°C); growth in one or more of $CuSO_4$, 8-azaguanine or 2,6-diaminopurine; and lipase production are, in general, characteristics of *L. biflexa* and *Leptonema* (Table 1). Flagellar antigens have also been grouped into distinct relationships. Related isolates have similar LPS profiles on polyacrylamide gel electrophoresis (PAGE). For many years it was wrongly assumed that all leptospires were metabolically and probably genetically identical because they appeared to be morphologically and culturally similar, differing from one another only in their serovar-specific antigens. Some early studies should now be repeated using members of different species to understand the extent of intra- and interspecies differences and to test the validity of extrapolating research results to different leptospires.

LABORATORY ISOLATION AND IDENTIFICATION

Laboratories may need to look for leptospires in clinical or pathological specimens from humans or animals, or from environmental sources. They also may need to grow them for research or industrial purposes. Leptospires are so hard to see and so hard and slow to grow that conventional bacteriological diagnostic procedures (microscopy of stained preparations and culture on solid media) are not practicable. Dark field microscopy of diagnostic, including environmental, specimens is

Table 1 *Species, serovars, serogroups, and phenotypes of some leptospires*[a]

a) The species identity of some strains representative of more than 250 recognized serovars in major serogroups is summarized from several sources. The species identity of many more strains awaits formal publication. Isolates were identified initially by serovar. The same serovar occurs in more than one species. Not all serogroups are represented in this table. Complete serovar lists to date were published by Kmety and Dikken (1993) and Faine et al. (1999).
b) Serogroups indicated by the number in the column. 1, Australis; 2, Autumnalis; 3, Ballum; 4, Bataviae; 5, Canicola; 6, Celledoni; 7, Cynopteri; 8, Djasiman; 9, Grippotyphosa; 10, Hebdomadis; 11, Icterohaemorrhagiae; 12, Javanica; 13, Leptonema; 14, Lyme; 15, Mini; 16, Pomona; 17, Pyrogenes; 18, Sarmin; 19, Sejroe; 20, Semaranga; 21, Tarassovi; 22, Turneria; 23, Hurstbridge; 24, Ranarum; 25, Manhao.
c) Nonpathogenic. Includes species *hollandia* and *wolbachia*. Other nonpathogens are listed in Faine et al. (1999).
d) G + C ratio mol% and phenotypes, compiled from various sources. In some cases the only isolate studied was an old laboratory strain. *L. biflexa* G + C: (36.0 ± 0.3)–(37.6 ± 0.7). e) Type hardjobovis.
f) Type hardjoprajitno. *L. alexanderi*, serogroup Manhao, serovar Manhao 3, type strain L60^T (ATCC 700520^T) (Brenner et al. 1999) and *L. fainei*, serogroup Hurstbridge, serovar Hurstbridge, reference strain BUT^T (Billinghurst et al. 1994; Perolat et al. 1998) are new species.

technically difficult because particles or other bacteria in the specimens scatter light and impede visualization. Microscopy is presumptive and immediate; culture is definitive if successful, but slow, taking up to 3–4 weeks for growth and days to weeks for identification.

Immunofluorescent staining is rapid and specific if the serovar or serogroup of the leptospires is known or suspected, or pools of antisera are used. Direct PCR can be carried out on specimens. PCR is relatively fast, taking hours or a few days; it is valuable for rapid identification of isolates.

Types of specimens

CLINICAL AND PATHOLOGICAL DIAGNOSTIC SPECIMENS

Similar specimens are, in general, investigated for leptospirosis in humans and in animals. The methods are the same in principle, and almost the same in practice, for both (Faine et al. 1999; Levett 2001; Weyant et al. 1999).

Blood cultures, taken aseptically from febrile patients or animals, are inoculated into EMJH medium containing sodium polyanethane sulfonate (and β-lactamase if treatment with penicillin has begun) at dilutions of at least 1 volume (from 0.1 to 1.0 ml) to 100 volumes of medium. Special media are used for fastidious leptospires. Cerebrospinal fluid (CSF) and urine are cultured similarly; urine specimens must be alkaline when passed and collected aseptically. Cultures are incubated at 30°C and examined macroscopically daily for up to 3 weeks and microscopically to confirm growth when it is suspected, or before discard. Subcultures are made into volumes of 5–10 ml of liquid media with further subcultures every 3–14 days at first; solid media are not used in general. The tissues most usually examined in animals are kidneys, genital tract organs, semen, abortion products, and placentas; examination of human tissues is rare in nonfatal leptospirosis. Urine and autopsy specimens and field specimens from animals are often contaminated; inhibitors such as cycloheximide, bacitracin, neomycin, polymyxin B, and rifampin in the media prevent or retard the growth of other bacteria. Tissues from autopsies, or rarely from biopsies, are ground aseptically with sterile buffered (pH 7.2) saline diluent and the supernatant cultured as above. Carryover of tissue debris can make the medium anaerobic and prevent leptospiral growth (see Faine et al. (1999) and Weyant et al. (1999) for details of diagnostic cultures).

ENVIRONMENTAL SPECIMENS – WATER, MUD, AND SOIL

Leptospires, including pathogens, persist in water, soil, mud, and effluents. Detection by direct dark field microscopy is of limited value. Immunofluorescent staining can detect leptospires without regard to viability. Water can be filtered through a bacteriological filter of 0.22 μm average pore diameter (APD) which will let leptospires through the pores. Soil, mud, and similar samples can be shaken with sterile water and the sediment centrifuged. The supernatant or eluate is filtered as above. The filtrates are cultured in liquid or on solid media. Successful cultures can be achieved by using media with inhibitors (see above). Alternatively, the filtrate or water may be inoculated in a small area in the middle of the surface of a plate of solid medium. After incubation, growth of leptospires will spread in a ring, centrifugally from the inoculation site, allowing subculture from the growing edge. Such cultures need to be checked for purity because more than one strain of leptospires may occur in these specimens. Special high sodium media have been described for culturing halophilic leptospires.

Identification of isolates; typing methods

Cultures, once grown, need to be checked for purity and identity. Purity can be checked by plating on solid media, remembering that a pure culture can have more than one colony type. Colony type is not usually included in criteria for identification or classification. The usual method for testing serological identity is by microscopic agglutination test (MAT).

A reference antiserum is serially diluted in phosphate buffered saline, pH 7.2, usually in two-fold steps starting at one or more steps in a 1 in 10 dilution series, in volumes of 25 μl in microtitration trays. An equal volume of the culture to be tested, standardized for density, is added and the covered tray incubated at a noncritical room temperature or 30°C for 1.5–2.0 h. A loopful from each dilution is examined microscopically under dark field. Alternatively, if tests are performed in flat-bottom trays free of scratches, they may be read directly in the tray using a long working-distance microscope objective. Agglutination is noted and scored as an approximate percentage of the leptospires agglutinated. The end point is 50 percent agglutination. ELISA tests are also used as serological methods for identification, in reactions with standard antisera (Dikken and Kmety 1978; Faine et al. 1999; Levett 2001; Weyant et al. 1999). Serological identification should be done at least to serogroup level, but to serovar level if possible, and in addition, to subtype within the serovar if appropriate. The lengthy standardized procedure begins with MAT using various reference antisera from different serogroups, to find one that agglutinates it to titer or close to titer, repeated similarly with antisera reacting to single serovars. Batteries of pooled sera are used initially. Homologous antisera to the new strain are produced in rabbits. These antisera and the reference antisera to the reacting reference strain are then

absorbed and cross-absorbed with both the new strain and the reacting reference strain. The absorbed antisera are titrated in MAT using homologous and heterologous strain antigens. The new strain is regarded as the same as the old strain if the residual titers after cross-absorption both ways are 10 percent or less. A simplified acceptable procedure is to use batteries of reference monoclonal sera which can identify to at least serogoup level immediately. Since the epitopes are not necessarily characteristic nor unique for a single serovar, pools of monoclonals are used to detect epitopes whose pattern of reaction is specific for a serovar. The use of monoclonal antibodies supplants the methods employing 'factor sera' for 'factor analysis', an analogous form of identification using serovar-specific pools of absorbed antisera.

It is important to identify the species as well as the serovar when describing or researching a leptospire because characteristics specified by species may be different for a given serovar. The reference method for bacterial speciation remains the degree of homology at DNA level (Wayne et al. 1987). However, the procedure is cumbersome and unsuitable as a tool for routine use. RFLP based on PCR amplification of either 16S rRNA or 23S rRNA genes has been shown to group strains in general agreement with their correct species designation (Perolat et al. 1994; Ralph et al. 1993). Probes derived from random primed PCR fingerprints were also able to discriminate at species level (Letocart et al. 1997).

At subspecies level, the first widely used method was restriction endonuclease analysis (REA) of whole genomic DNA (Marshall et al. 1981). Despite the difficulty in reading complex restriction profiles due to the large number of fragments generated, the technique has provided useful epidemiological information. For example, REA first identified the Hardjobovis and Hardjoprajitno subtypes now known to belong to different species, as well as allowing discrimination of three subtypes of Hardjobovis (Thiermann et al. 1986). Similar subtypes have been identified within other serovars. All leptospiral genomes appear to have multiple copies of a range of insertion sequences; some of these have been used as targets for identification and molecular typing schemes (Zuerner et al. 1995; Zuerner and Bolin 1997).

Interestingly, and perhaps unexpectedly, the analysis by PFGE of restriction fragments generated by digestion with rare cutting enzymes such as *Not*I or *Sgr*AI yielded unique patterns for most serovars (Herrmann et al. 1992; Herrmann and Saint-Girons 1993; Herrmann 1994). In reality, PFGE has become accepted as the most appropriate and accurate molecular typing method. A disadvantage is the need for specialized equipment and expertise. For this reason, a range of methods based on random PCR amplification of chromosomal DNA has been reported (Faine et al. 1999; Levett 2001); in general they show good correlation with PFGE and can be performed readily by any laboratory with PCR capacity.

SUSCEPTIBILITY TO ANTIMICROBIAL AGENTS

General and environmental agents

Leptospires and leptonemes are destroyed by heat above about 42°C, acid (below about pH 6.5), alkali (above about pH 8.0), heavy metals, halogens, detergents (including soaps, free fatty acids, bile salts), drying and reducing conditions (*E*h below about −0.300 mV). They can survive chilling to 4°C or freezing to −20°C in tissues (including kidneys in butcher shops). In the laboratory they can be cryopreserved in liquid nitrogen and have been preserved lyophilized. Cultures stored in sealed tubes in the dark at room temperatures below about 40°C remain viable for months; leptospires have been grown after 8 years of storage.

Antibiotics and metabolic antagonists

All classes of antibiotics except chloramphenicol and rifampin kill leptospires. Penicillin and doxycycline are used widely in therapy; the latter has also been used for chemoprophylaxis. Streptomycin and dihydrostreptomycin are used for eliminating leptospires from the kidneys of carrier animals. Resistance to any antibiotic has not appeared as a clinical problem, probably because there is no human-to-human transmission. Individual isolates of leptospires are not usually tested for susceptibility to antibiotics. The selective use of purine and pyrimidine inhibitors for classification has been mentioned above.

PATHOGENICITY AND VIRULENCE FACTORS

This topic is reviewed in detail in Faine et al. (1999) and dealt with in the context of infection, pathogenesis, and diagnosis.

Role in the normal flora of humans

The natural habitat of leptospires is in the environment; they are not known to be part of the normal flora of humans or animals. Leptospires infect humans only by accident of contact with a contaminated environment; spread from humans to other humans is almost unknown apart from congenital infection. Animals that survive acute systemic infection may become renal carriers that excrete leptospires in the urine; the carrier state is not established without prior generalized clinical or subclinical infection.

'Pathogenic' and 'nonpathogenic' leptospires – virulence and virulence factors

Large numbers (approximately 10^{10}) of leptospires of either the nonpathogenic species *L. biflexa* or the pathogenic species are dermonecrotic and cytotoxic. *L. biflexa* and avirulent pathogenic leptospires do not survive for long in the body because naturally occurring immunoglobulins kill them in the presence of lysozyme and complement (Faine and Carter 1968). They are then phagocytosed. Virulent leptospires survive possibly because the antigens reacting with these opsonic immunoglobulins are not expressed or not available on the surface. Virulent leptospires, growing in an animal host, may also be able to survive in macrophages, in which they induce apoptosis (Merien et al. 1998). This activity was lost after a single in vitro passage. An outer membrane lipoprotein LipL36 was synthesized at 30°C but not at 37°C (Nally et al. 2001b), while some other membrane associated proteins or lipoproteins, including LipL41, LipL32, and OmpL1, are produced at either temperature in culture, or only at 37°C and during growth in an animal infection model (Cullen et al. 2002; Haake et al. 1998, 2000; Nally et al. 2001b). LipL41 and OmpL1 were synergistically protective in experimental infections (Haake et al. 1999). The surviving leptospires grow in the blood and selected tissues to a critical concentration correlated with the appearance of lesions. Growth of leptospires in the body stops when opsonizing antibodies appear, 3–10 days after inoculation, followed immediately by clearance by local and central reticuloendothelial phagocytosis. The opsonins are directed to specific LPS epitopes. Nothing is known of the genetics or regulation of expression of the ability to survive natural antibodies (Faine et al. 1999).

The primary lesions in leptospirosis consist of damage to the endothelial cells of small blood vessels, leading to leakage of plasma and hemorrhages. Localized acute inflammation and polymorphonuclear exudates are not seen initially in acute leptospirosis. The consequences of the damage to blood vessels are ischemia to the cells and organs dependent on the disturbed blood supply and the primary and secondary effects of sometimes massive hemorrhage. Almost any organs or body systems can be affected; the process is essentially the same in all animals. Renal tubular necrosis is common, sometimes followed by scarring during repair, and the localization of leptospires on the luminal surface of the tubular cells, where they grow and are excreted in urine (Faine et al. 1999).

The lesions are probably caused by the action of one or more toxins, one of which is a cytotoxic and antigenic GLP (see Chemical composition above) extractable from leptospires, that can be identified in lesions; convalescent patients' antisera react with GLP. GLP activates cytokines (Diament et al. 2002). LPS does not appear to play a significant part in pathogenesis; it is very weakly pyrogenic and does not produce the lesions that GLP does. The effects of GLP may be due to the unusual unsaturated fatty acids of leptospiral origin acting as competitive inhibitors of the incorporation of normally occurring fatty acids in the target cell membranes (Vinh et al. 1986), resulting in a disturbance of Na^+,K^+-ATPase activity in renal tubular cells (Younes-Ibrahim et al. 1997b). Hemolysins (sphingomyelinases) produce holes in erythrocyte and probably other cell membranes (Lee et al. 2002; Thompson 1986).

Microbiological aspects of natural and acquired resistance

Immunity in initial or subsequent infection appears to be wholly humoral and serovar-specific, dependent on opsonization mediated by immunoglobulins directed to LPS epitopes. Phagocytosis depends on antibodies to LPS. Although it is generally agreed that antibodies are of prime importance in protection from initial acute infection, a killed Hardjobovis vaccine stimulated a Th1 response in protected cattle (Naiman et al. 2001).

BARTONELLA

HISTORICAL PERSPECTIVE

The first recognized member of the genus *Bartonella* is *B. bacilliformis*, described by Alberto Barton in 1905. The Peruvian physician observed the presence of intraerythrocytic bacilli in blood smears of patients suffering from Carrión's disease (Barton 1905). Carrión's disease is a biphasic infection that occurs endemically in the valleys of the South American Andes of Peru, Columbia, and Ecuador and is transmitted by the blood sucking sandfly *Lutzomya verrucarum*. The acute stage of the infection is known as 'Oroya fever,' a highly febrile illness followed by a severe acute hemolytic anemia. It was named after a dramatic outbreak during the construction of the Peruvian railroad from Lima to the mining center La Oroya in 1870. More than 8 000 of the 10 000 laborers fell ill and most of them died. Several weeks or months later, many of those workers who survived the acute febrile stage of the illness developed wart-shaped or hemangioma-like skin lesions, the so-called 'Verruga peruana'.

In August 1885, the 26-year-old Peruvian medical student Daniel Alcides Carrión inoculated himself with secretions from a Verruga peruana skin lesion of a 14-year-old patient. Three weeks later he developed high fever followed by severe anemia. Eighteen days later Daniel Carrión died from Oroya fever and demonstrated with this heroical self-experiment the common infectious nature of Oroya fever and Verruga peruana (Schultz 1968; Garcia-Caceres and Garcia 1991).

In 1926, successful cultivation of the causative pathogen on blood containing media was reported and, in honor of Barton, named *Bartonella bacilliformis* (Noguchi and Battistini 1926).

In 1916, during the First World War, a newly recognized disease was first reported from the eastern front of the German army in Wolhynia (today part of the Ukraine) by two German military physicians, Hiss and Werner (Werner and Haenssler 1916). The soldiers suffered from relapsing fever with body temperature up to 40°C (in mean 6–10 attacks), headache, myalgia, bone pain, moderate anemia, and occasionally hepatosplenomegaly. Due to the 5-day periodic recurrence of the fever the illness was known as 5-day-fever, febris quintana or trench fever, but also as Wolhynia fever or Werner–Hiss disease (Munk and da Rocha Lima 1917a, b). To demonstrate the infectious nature of the disease, the two German physicians Benzler and Werner inoculated themselves intramuscularly with blood from a patient suffering from trench fever (Werner et al. 1916). After an incubation period of 20 and 23 days respectively, both physicians fell ill. In contrast to Carrión's disease, however, trench fever is a self-limiting illness and the physicians recovered from their self-experiment.

Henry da Rocha Lima was a Brazilian microbiologist, who worked between 1910 and 1928, together with

Stanislaus von Prowazek, at the Institute for Tropical Medicine in Hamburg, Germany. In 1914, the two microbiologists were told to investigate an outbreak of murine typhus in Cottbus, where both became infected. In contrast to von Prowazek who died on 17 February 1915 of murine typhus, Henry da Rocha Lima survived and described the etiologic agent *Rickettsia prowazekii*. On this occasion, da Rocha Lima was also confronted with trench fever (de Cerqueira Falcao 1966). He recognized very soon that the body louse was the main vector for transmission of trench fever and showed in his investigations that the agent of trench fever (named by him *Rickettsia pediculi*) was found, in contrast to *R. prowazekii*, mainly extracellularly in the gastrointestinal tract of the infected lice. He detected *Rickettsia pediculi* in the body lice of 73 percent of trench-fever patients, whereas only 18 percent of healthy soldiers had been infested with infected lice (Munk and da Rocha-Lima 1917b). In 1961, nearly a half century later, Vinson and Fuller were able to culture the agent of trench fever on blood containing solid media and, in honor of Henry da Rocha Lima, the strain was renamed subsequently in *Rochalimaea quintana* (Vinson and Fuller 1961).

THE GENUS *BARTONELLA*

Members of the family Bartonellaceae belong to the α-2 subdivision of the Proteobacteria, showing a close evolutionary relationship to the human pathogen *Brucella* and to the plant pathogens *Rhizobium meliloti* and *Agrobacterium tumefaciens* (Marston et al. 1999). Depending on the *Bartonella* species, the genome size varies between 1 600 and 2 174 Mb and the G + C (guanine-plus-cytosine) content of the genome ranges from 39 to 41 percent (Roux and Raoult 1995).

In recent years, the classification of the family of Bartonellaceae was revised several times. In 1993, the genus *Rochalimaea*, including the four species *R. quintana*, *R. vinsonii*, *R. henselae*, and *R. elizabethae* was removed from the family Rickettsiaceae and transferred to the family Bartonellaceae, which by then consisted of a single species, namely *B. bacilliformis* (Brenner et al. 1993). Based on the 16S rRNA gene sequencing, DNA hybridization, G + C content, and phenotypic characterization studies, Birtles et al. (1995) proposed the unification of the genera *Grahamella* (consisting of the two species *G. talpae* and *G. peromysci*) and *Bartonella* and defined three new species, namely *B. doshiae*, *B. grahamii*, and *B. taylorii*.

In the following years, the number of identified *Bartonella* species increased considerably. The widespread occurrence of *Bartonella* in the bloodstream of different mammals has resulted in the description of several new *Bartonella* species. Currently, the family Bartonellaceae consists of 20 *Bartonella* species which are listed in Table 1.

Table 1 *The family of Bartonellaceae, their natural reservoir and mode of transmission*

	Bartonella species	Year of description	Reference	Reservoir	Vector
1	*B. bacilliformis*	1905	(Barton 1905)	human	sandfly
2	*B. talpae*	1911	(Brumpt 1911)	mole	unknown
3	*B. quintana*	1917	(Schmincke 1917)	human	body louse
4	*B. peromysci*	1942	(Tyzzer 1942)	deer, mouse	unknown
5a	*B. vinsonii* spp. *vinsonii*	1946	(Baker 1946)	vole	vole ear mite
6	*B. henselae*	1992	(Regnery et al., 1992a; Welch at al., 1992)	cat	cat flea
7	*B. elizabethae*	1993	(Daly et al. 1993)	rat	unknown
8	*B. grahamii*	1995	(Birtles et al. 1995)	mouse, vole	unknown
9	*B. taylorii*	1995	(Birtles et al. 1995)	mouse, vole	unknown
10	*B. doshiae*	1995	(Birtles et al. 1995)	vole	unknown
5b	*B. vinsonii* spp. *berkhoffii*	1996	(Kordick et al. 1996)	dog	ticks
11	*B. clarridgeiae*	1996	(Lawson and Collins 1996)	cat	cat flea
12	*B. tribocorum*	1998	(Heller et al. 1998)	rat	unknown
13	*B. alsatica*	1999	(Heller et al. 1999)	rabbit	unknown
14	*B. koehlerae*	1999	(Droz et al. 1999)	cat	unknown
5c	*B. vinsonii* spp. *arupensis*	1999	(Welch et al. 1999)	mouse	ticks
15	*B. birtlesii*	2000	(Bermond et al. 2000)	mouse	unknown
16	*B. schoenbuchii*	2001	(Dehio et al. 2001)	roe deer	unknown
17	*B. bovis* (=*B. weissii*)	2002	(Bermond et al. 2002)	cattle/cat	unknown
18	*B. capreoli*	2002	(Bermond et al. 2002)	roe deer	unknown
19	*B. washoensis*	2003	(Kosoy et al. 2003)	ground squirrels	unknown
20	*B. chomelii*	2004	(Maillard et al. 2004)	cattle	unknown

Note that 5a, 5b, 5c are subspecies which belong to the same *Bartonella* species.

Microscopically, all *Bartonella* spp. are gram-negative, pleomorphic, slightly curved bacilli of approximately 1–2 – 0.5 μm with a distinct tendency to autoagglutination (Figure 1). Growth of *Bartonella* spp. is obtained on fresh media supplemented with 5 percent sheep or rabbit blood in the presence of 5 percent CO_2. The optimal incubation temperature varies from 25°C (*B. bacilliformis*) to 35°C (other species). The aerobic, highly fastidious organisms are oxidase- and indole-negative, and inert in carbohydrates metabolism. The G + C content ranges from 38.5 to 41 mol%.

Electron microscope examination of *B. bacilliformis*, *B. clarridgeiae*, *B. schoenbuchii*, and *B. capreoli* demonstrated the presence of multiple unipolar flagella. Polar structures resembling fimbriae have been observed in *B. tribocorum* and *B. alsatica*, whereas most strains of *B. henselae* and *B. quintana* have peritrichous pili, which are associated with cytoadherence. *B. bacilliformis* and *B. henselae* (and probably also *B. quintana*, *B. doshiae*, and *B. grahamii*) are known to produce bacteriophage-like particles that package 14 kbp segments of the host chromosome (Anderson et al. 1994; Barbian and Minnick 2000).

RESERVOIR AND MODES OF TRANSMISSION

The natural reservoir of the different *Bartonella* species and the mode of transmission are presented in Table 1. The currently available data indicate a strong association of a given *Bartonella* sp. with a specific host, i.e. *B. bacilliformis* and *B. quintana* with humans, *B. henselae*, *B. clarridgeiae*, and *B. koehlerae* with cats, *B. vinsonii* subsp. *berkhoffii* with dogs and coyotes, *B. alsatica* with wild rabbits, *B. tribocorum* with rats, and *B. schoenbuchii* and *B. capreoli* with roe deer. However, factors which are involved in the determination of host specificity have not been described. Simultaneous infection with more than one *Bartonella* sp. has been demonstrated in cats and rodents (Figure 2).

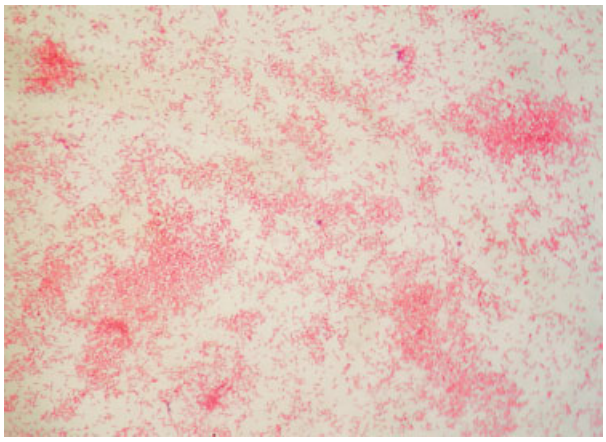

Figure 1 *Microscopic presentation of Gram-stained* B. henselae*: small gram-negative, pleomorphic, slightly curved rods.*

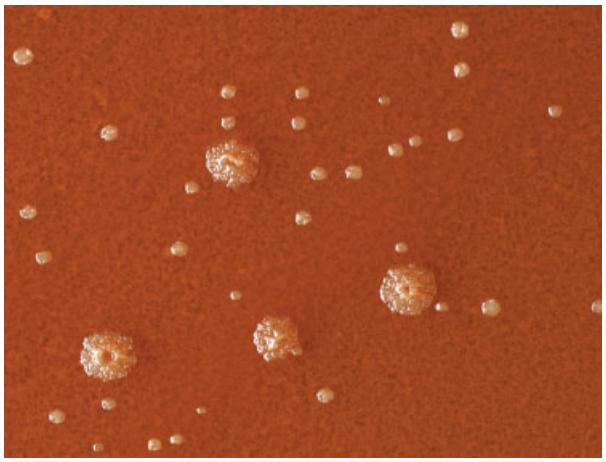

Figure 2 Bartonella henselae *(small colonies) and* B. clarridgeiae *(rough colonies) isolated from a blood culture of a cat.*

Several ectoparasites have been implicated in transmission of *Bartonella* species. *Bartonella bacilliformis* is transmitted to humans by the sandfly *Lutzomyia verrucarum*, *B. quintana* by the human body louse *Pediculus humanus,* and *B. henselae* by scratches or bites from bacteremic cats or by the cat flea *Ctenocephalides felis*.

Bartonella henselae is transmitted from bacteremic cats to specific-pathogen-free cats by the cat flea, and the agent can be cultured from flea feces up to 9 days after feeding on infected blood. Experimental infection of cats by intradermal inoculation with infected flea feces was also shown. In contrast, when uninfected cats were housed with *B. henselae* infected cats in an ectoparasite-free environment, no evidence of *Bartonella* transmission was noted. Although still not proven, there is also strong evidence that transmission of *B. henselae* to humans occurs via infected flea feces, either by contaminated claws or teeth after cat scratches or bites, or directly by inoculation of infected flea feces after flea-bite by scarification of the skin or through conjunctival contact. Although cat fleas frequently infest dogs within a household which also contains infected cats, these organisms have not been isolated from the blood of asymptomatic dogs until now (Breitschwerdt and Kordick 2000).

All *Bartonella* species have been isolated from the bloodstream of their host. Detailed investigations concerning the presence of *B. henselae* in the blood of cats have demonstrated that the bacteria may be found intracellularly in 2.9–6.2 percent of the erythocytes in bacteremic animals (Kordick and Breitschwerdt 1995; Rolain et al. 2001), but also extracellularly in infected animals (Guptil et al. 2000).

In veterinary medicine, the most extensive *Bartonella* studies have involved domestic and feral cats. The rate of bacteremic cats and the seroprevalence of *B. henselae* antigen is much higher (40–70 percent) in cats that live in warm, humid regions of the world, in which severe

flea infestation is expected (Breitschwerdt and Kordick 2000). Feral cats are more likely to be infected than pet cats from the same region. Although some of these animals may be bacteremic over a period of more than 1 year, cats are usually healthy and asymtomatic (Sander et al. 1997).

There is strong evidence that ticks play an important role in the transmission of *Bartonella* species among animals. However, the role of ticks in transmission to humans remains undefined. Elimination of fleas, ticks, and body lice may interrupt transmission of *Bartonella* species to humans and among animals.

Eight of the 20 currently described *Bartonella* spp. are known to be related to human diseases (Table 2).

BARTONELLA BACILLIFORMIS AND CARRIÓN'S DISEASE

Clinical manifestations

B. bacilliformis is a fastidious hemotropic organism which invades and destroys red blood cells. The organism appears to have a restricted geographical distribution to specific altitudes (500–3 200 m) of the mountainous regions in the South American Andes of Peru, Ecuador, and Colombia (Gray et al. 1990; Alexander 1995; Amano et al. 1997; Cáceres-Ríos et al. 1995). However, outbreaks have also been reported in formerly nonendemic areas over recent years and bartonellosis (Carrión's disease) appears to be an emerging disease with an expanding geographical distribution. Outbreaks of bartonellosis were reported in late 1996 in Utcubamba River Valley in the Amazonas Department in Northern Peru (Kosek et al. 2000) and in 1998 in the Urubamba River Valley (Cusco) of Peru (22 case-patients, Ellis et al. 1999), regions not previously considered endemic for this disease, as well as in 1997 in Zamora Chinchipe Province in Ecuador involving 19 cases (Cooper et al. 1997). In a prospective, population-based study of bartonellosis in the Caraz District, an endemic area in Peru, the incidence of bartonellosis was 12.7/1 000 persons/year and the prevalence of asymptomatic *B. bacilliformis* bacteremia was 0.5 percent. The incidence was highest in children, particular young children aged 0–4 years (38/100 person-years) and 5–10 years (16/100 person years). The age-related incidence pattern found suggests an acquired immunity following exposure to this agent (Chamberlin et al. 2002).

Bartonella bacilliformis is transmitted by the bite of the sandfly *Lutzomyia verrucarum*. In the human host, *B. bacilliformis* causes a biphasic disease with two distinct clinical forms.

The first and acute phase of bartonellosis, named Oroya fever, has an incubation period of usually 1–3 weeks (range 7–100 days) and is characterized by fever, headache, hemolytic anemia, pallor, myalgia, and arthralgia. It may also be associated with generalized or regional lymphadenopathy (1.5–3 cm, nonpainful, nonadherent), severe thrombocytopenia, altered mental status, seizures, meningeal signs, hemiparesis, and hypoxic complications of delerium and coma. Funduscopic abnormalities including flame-shaped hemorrhagies, cotton-wool exudates, and papilledema have been described, as well as pericardial and pleural effusions and cardiomegaly (Maguina and Gotuzzo 2000). The severity of this stage ranges from subclinical infection to an acute hemolytic crisis, when *B. bacilliformis* invade up to 90–100 percent of erythrocytes and causes a massive destruction of red blood cells in all organs

Table 2 *Currently recognized human diseases related to* Bartonella *species*

	Bartonella spp.	Associated human diseases	Year of description	Reference

(Reynafarie and Ramos 1961). Untreated, Oroya fever is often life threatening. This acute stage may be accomplished by a variably-induced immunosuppression, and may be associated with the presence of secondary infections. Up to 35 percent of Oroya fever patients may develop infectious complications, including systemic salmonellosis (*Salmonella* Typhi and enteric *Salmonella*), shigellosis, reactivation of toxoplasmosis, disseminated histoplasmosis (*Histoplasma capsulatum*), malaria, and infections caused by *Staphylococcus aureus*, *Enterobacter* spp., *Pneumocystis jiroveci (carinii)* (Colichón and Cuandra 1954; Cuandra 1956; Maguina et al. 2001). After the acute phase, recurring episodes of fever and transitory pain in the bones, joints, and muscles may occur (Ricketts 1949).

Only limited data on the course of bartonellosis during pregnancy are available. One study noted that of five pregnant patients suffering from acute bartonellosis, two died and only one had a successful outcome of pregnancy (Maguina et al. 2001). Bartonellosis seems to bear a great risk for both the pregnant mother and the fetus.

During the Oroya fever outbreak of 1871 a fatality rate of 80 percent was reported and during the Shumpillan outbreak in 1990 (Gray et al. 1990) the patient fatality rate in untreated cases was 88 percent. A recent retrospective hospital-based study reported a mortality rate of 8.8 percent despite appropriate antibiotic treatment (Maguina 1993). In a population-based study during the Utcubamba outbreak in 1996 the case fatality rate differed enormously from those previously reported and was only 0.7 percent. In the same study, the attack rate of Oroya fever was 13.8 percent and that of Verruga peruana 17.6 percent (Kosek et al. 2000).

Following the acute clinical manifestations of Oroya fever, a period of dormancy or latency, generally noted for months, may ensue. Subsequently, patients may develop the second, chronic eruptive stage, named verruga peruana ('Peruvian warts'). Although verruga peruana was originally thought to occur only in patients who had suffered and recovered from Oroya fever, some recent studies found that 5 percent of the patients with Verruga peruana had no history of an acute febrile illness months before the skin eruptions. The acute febrile stage is rarely seen among the natives in endemic regions, on which Verruga peruana is common. Three different types of cutaneous manifestations were observed: (1) the miliary lesions typically consist of multiple 1–4 mm papular, erythematous, round lesions that are frequently associated with pruritus; (2) the nodular (subdermic) lesions appear as a subdermal nodule without changes in the overlying skin, without pruritus and usually few in number; and (3) the mular skin lesions are typically >5 mm in diameter, erythematous, and bleed easily. The verrugas vary in size and number and occur predominantly on the head and distal extremities. Lesions on the conjunctiva and on the nasal and oral mucosa have also been described (Maguina et al. 2001; Welch and Slater 1999).

In a population-based study, the peak prevalence of the appearance of new skin lesions occurred 1 month after the peak prevalence of the febrile illness. The incidence of Verruga peruana was highest in children aged 7–12 years (Kosek et al. 2000). The verrugas may persist for several months to years, but this stage is benign and self-limiting.

In the outbreak study performed by Kosek et al. (2000), 77.5 percent of the native population were found to have evidence of prior infection with *B. bacilliformis*. The seroprevalence ranged from 70.4 percent in children aged <6 years to 85.1 percent in patients aged >55 years. In the same study, the majority (56.4 percent) of seropositive patients reported no illness or new skin lesions during the past year. Serological investigations of healthy volunteers living in an endemic area for *B. bacilliformis* revealed that 45 percent of the people tested were seropositive (Chamberlin et al. 2000).

Public health control measures have included education in endemic areas and the use of insecticides. Visitors going to endemic regions for *B. bacilliformis* should be aware of preventive measures against bartonellosis, e.g. protection against exposure to sandflies, wearing long-sleeve shirts and pants, using insect repellent, and reducing outdoor activities around dusk and dawn when sandflies are most active.

Diagnosis

LABORATORY DIAGNOSIS

For the diagnosis of acute Oroya fever, thin-film blood smears are stained with Giemsa stain and examined by light microscopy for the presence of intra- or extra-erythrocytic coccobacillary bacteria (magnification $\times$1 000). Using bacterial isolation as the standard, sensitivity, specificity, and positive predictive value of thin blood smears were found to be 36, 96, and 44 percent, respectively (Ellis et al. 1999). The percentage of infected red blood cells range from 2 to 100 percent (mean 61 percent) (Maguina et al. 2001) (Table 3).

Only few data concerning the laboratory parameters during bartonellosis have been published. Increased levels of aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and total bilirubin have been reported.

CULTURAL AND BIOCHEMICAL CHARACTERISTICS

B. bacilliformis can be isolated from blood and tissue specimens (spleen, liver, lymph nodes, skin, cerebrospinal fluid (CSF)) on a variety of media containing fresh blood or hemoglobin (e.g. Columbia blood agar

Table 3 *Clinical symptoms in patients with Oroya fever (acute phase of bartonellosis) and verruga peruana (second, chronic stage of bartonellosis) (modified after Ellis et al. 1999 and Maguina et al. 2001)*

–, not reported.

incorporating 10 percent horse blood; Colichon's medium consisting of soy agar plus sheep hemoglobin plus alanine). Cultures should be incubated at 25–28°C for at least 4 weeks in a humid atmosphere. In a study performed by Maguina et al. (2001), the mean time for positive blood cultures was 18 days (range 12–29 days) and isolates of *B. bacilliformis* were also obtained from lymph nodes and from CSF cultures. In the acute phase of bartonellosis, *B. bacilliformis* has been isolated from blood cultures in 71 percent of the cases, whereas in the eruptive-phase bartonellosis thin-film blood smears and blood cultures have been positive in 13 percent of the patients.

Morphologically, *B. bacilliformis* occurs in young cultures mainly in the form of short rods arranged singly, in pairs, in chains, clumps, or chains and clumps. In older cultures coccoid forms predominate. However, there is a considerable degree of pleomorphism. The rods are 0.3–1.5 μm long and 0.2–0.5 μm broad, motile and a tuft of at least ten flagella can be demonstrated at one pole. Ultrathin sections of red corpuscles examined by electron microscopy show that the organisms are situated inside the corpuscles, as well as on the surface, and that they have a trilaminar cell wall.

On solid media, growth occurs either in the form of minute, circular colonies, or as an opaque, finely granular, mucoid film that has a tendency to outgrow the original boundaries of the inoculum. *Bartonella bacilliformis* growth is strictly aerobic at a temperature of 25 to >28°C. It prefers a pH of 7.8, ferments no sugar and survives in semisolid medium at −70°C for years and at 25–28°C for several weeks (Weinman 1968). For biochemical reactions, see also Table 5.

POLYMERASE CHAIN REACTION AND GENOTYPING

Polymerase chain reaction (PCR) methods have been used in few studies to detect *B. bacilliformis* DNA in blood specimens. However, the sensitivity of this method for diagnosis of *B. bacilliformis* infection is currently unknown (Chamberlin et al. 2002). First genotyping studies of isolates obtained from different regions in Peru revealed six genotypes of *B. bacilliformis* (Birtles et al. 2002). Further studies are needed to improve our understanding of the epidemiology and the clinical importance of these different genotypes.

SEROLOGY

Detection of antibodies against *B. bacilliformis* seems to be more reliable in patients suffering from Verruga peruana than in patients with the acute phase of bartonellosis. Mallqui et al. (2000) have described an immunoblot test that uses sonication of whole *B. bacilliformis* and reported 94 percent sensitivity for patients with eruptive-phase bartonellosis and 70 percent sensitivity for patients with acute bartonellosis; in healthy individuals, the test showed 100 percent specificity. A recently developed indirect fluorescence antibody assay (IFA) showed a sensitivity of 82 percent in detecting *B. bacilliformis* antibodies in acute-phase blood samples and a sensitivity of 93 percent when convalescent-phase sera were tested. The specificity of the test was 92 percent and the positive predictive value was 89 percent (Chamberlin et al. 2000). Serological crossreactivity has been noted between *B. bacilliformis* and *Chlamydia psittaci* and has been attributed to similarities in the structure of the lipopolysaccharides (Knobloch et al. 1988).

HISTOPATHOLOGY

Histologically, verruga peruana is characterized by endothelial cell proliferation and neovascularization. Fibrosis and involution occur. In Giemsa-stained verruga biopsy sections, organisms may be seen in the cytoplasm of vascular endothelial cells. The bacteria are best demonstrated by Warthin–Starry staining. Electron microscopic studies have shown that *B. bacilliformis* was found abundantly in the extracellular space of the florid lesions and that no organisms were present in the late resolving subcutaneous nodules (Bass et al. 1997a; Arias-Stella

et al. 1986). The microbial factors responsible for the pathogenesis of these lesions are unclear.

Treatment and susceptibility to antimicrobial agents

B. bacilliformis organisms in vitro are highly susceptible to a large number of antibiotics, including β-lactams, aminoglycosides, chloramphenicol, rifampin, macrolides, tetracyclines, cotrimoxazole, and fluoroquinolones (Sobraqus et al. 1999).

Chloramphenicol, given in a daily dosage of 2 g or more for 10–14 days, was established as the drug of choice for the treatment of Oroya fever in the 1950s (Urteaga and Payne 1955). In a recent study, successful treatment of the acute phase of bartonellosis with chloramphenicol was seen in approximately 95 percent of patients. However, chloramphenicol-resistant cases have been observed and treatment with chloramphenicol did not eliminate the patient's risk of the subsequent development of the eruptive phase of bartonellosis. Successful treatment of acute bartonellosis has also been reported with other antibiotics, e.g. penicillin, streptomycin, erythromycin, tetracycline, and recently with ciprofloxacin (Maguina et al. 2001).

Rifampin at a dosage of 10 mg/kg/day for 10–14 days is the drug of choice for patients suffering from Verruga peruana. Alternatively, streptomycin at a dosage of 15 mg/kg/day for 10 days may be given, but rifampin seems to be more effective (80 percent good response) compared to streptomycin (56 percent good response) (Maguina et al. 2001). More recently, ciprofoxacin (500 mg twice a day for 7–10 days) was successfully used for the treatment of multiple eruptive-phase lesions in adults (Maguina and Gotuzzo 2000).

Pathogenesis

The flagella of *B. bacilliformis* are an important component to allow invasion of human erythrocytes (Scherer et al. 1993). In bacterial culture supernatants, a small water-soluble molecule, called deformin factor or deformin, could be identified and was shown to cause deformation and invagination of red cell membranes, as well as formation of intracellular vacuoles (Derrick and Ihler 2001). Recently, a protein of *B. bacilliformis* with hemolytic activity has been detected (Hendrix 2000).

INFECTIONS DUE TO *BARTONELLA HENSELAE* AND *BARTONELLA QUINTANA*

Clinical manifestations

B. HENSELAE AND CAT-SCRATCH DISEASE

Cat-scratch disease (CSD) was first described in 1950 by Debré, a French physician, who described several patients with suppurative lymphadenitis following cat scratches (Debré et al. 1950). Since then, a large number of viral and bacterial organisms have been suspected as etiologic agents for CSD, including *Chlamydiae*, acid-fast bacteria, *Pasteurella* spp., herpes simplex virus, feline bacteria and viruses, and finally in 1988 *Afipia felis* (English et al. 1988).

In 1992, *B. henselae* was first proposed as the etiologic agent of CSD (Regnery et al. 1992b, c) and thereafter a large number of serologic, culture-, and molecular-based data confirmed this conclusion. Currently, CSD is nearly exclusively associated with *B. henselae*. Reports suggesting additional etiologic agents still await confirmation.

However, a large number of other infective agents are known to cause lymphadenopathy, e.g. staphylococci, streptococci, *Haemophilus* spp., *Mycobacterium* spp., *Francisella tularensis*, *Brucella* spp., *Treponema pallidum*, *Leptospira* spp., *Chlamydia* spp., *Toxoplasma gondii*, *Borrelia* spp., Epstein–Barr virus, cytomegalovirus, *Histoplasma capsulatum*, and others (Ridder et al. 2002; English et al. 1988). All these agents should be considered in the differential diagnosis of infective lymphadenopathy. Lymphoma is the most common malignancy that might be misinterpreted as CSD. So, in cases with atypical clinical presentations, or when the serological results are not indicative, surgical extirpation of the lymph node may be required for histopathological investigations.

Cat-scratch disease occurs worldwide in all ages, in children and adults. Most cases occur in late fall and winter (October–March), when a closer and prolonged contact to indoor cats occurs. Patients with cat-scratch disease are likely to own a cat aged 12 months or younger, and to have been scratched or bitten by a kitten. These cats are often found to be infested with cat fleas. Cat-scratch disease occurring in two or even in three siblings has been reported and was often associated with the acquisition of a new kitten in the household (Gonzalez et al. 2003; Sander et al. 1998c).

Cat-scratch disease is the typical clinical manifestation of a *B. henselae* infection in immunocompetent patients and appears in two different forms.

Typical cat-scratch disease

Typical cat-scratch disease is a benign and self-limited illness. Between 25 and 60 percent of patients report a primary cutaneous granulomatous lesion of 0.3–1 cm in diameter at the site of inoculation (Figure 3a). In a recent study performed by Ridder et al. (2002) only 57 percent of all CSD patients had been exposed to cats, suggesting that other vectors (e.g. cat fleas or even other parasites) may play an important role in transmission of *B. henselae* to humans (Table 4). Of the 61 CSD patients, 54 percent were female and 46 percent were male, and the age range was 4–89 years (median 33.9 years). The primary skin lesions occur 3–10 days after injury (scratches or bites) and precede the onset of

Figure 3 (a) *CSD patient: Primary granulomatous lesion at the site of inoculation a few days after cat scratch.* **(b)** *CSD patient (same patient as presented in panel* **(a)***: Supraclavicular lymphadenitis followed 4 weeks after a cat scratch.*

lymphadenopathy by 1–3 weeks (range 7–60 days). Regional lymphadenpathy is the most common clinical manifestation of CSD and the site of lymphadenopathy depends on the site of inoculation (Figure 3b). The head and neck (28–43 percent) and the axillary (38–49 percent) lymph nodes are most often affected, followed by supraclavicular, inguinal, cubital, epitrochlear, and other localizations. Lymphadenopathy at more than one anatomical site appears in 37–59 percent of all cases. Lymph nodes may increase in size (usually 1–5 cm in diameter or even larger) and number for up to 4–6 weeks. The whole extent of lymphadenopathy can be best documented by ultrasonography (Ridder et al. 2003). The usual duration of lymphadenopathy is approximately 2–4 months, and in some cases even longer. Only one-third of all patients presents with fever up to 40°C in the first days (up to 3 weeks) of the illness. Headache, weakness, weight loss, nausea, vomiting, sore throat, pharyngitis, anorexia, and hepatosplenomegaly may occur. In addition, maculopapular eruptions, erythema nodosum, and thrombocytopenic purpura have been observed (Ridder et al. 2002; Regnery and Tappero 1995; Anderson and Neuman 1997; Bass et al. 1997b; Carithers 1985; Hamilton et al. 1995).

Late in the course of illness, 10–15 percent of the lymph nodes may suppurate. In a recent study acute lymphadenopathy was diagnosed in 64 percent of the CSD patients, 18 percent had suppurated lymph nodes and 18 percent had chronic lymphadenitis of more than 3 months of duration (Ridder et al. 2002).

In summary, CSD must be considered in all cases of regional (acute or chronic) lymphadenopathy. Exposure to cats or cat fleas is the main risk factor. Cat-scratch disease may be more prevalent than previously realized. Unnecessary biopsy of the lymph node may be avoided by use of adequate serological examinations.

Atypical cat-scratch disease

Atypical cat-scratch disease is characterized by unusual manifestations of CSD and occurs in 5–25 percent of all infections. Parinaud's oculoglandular syndrome, neuroretinitis, encephalitis, hepatic granulomas, osteomyelitis, endocarditis, and pulmonary disease may occur, but these complications usually resolve without sequelae.

OCULAR MANIFESTATIONS

Parinaud's oculoglandular syndrome (POGS) occurs in 2–17 percent of all patients and manifests as unilateral, granulomatous conjunctivitis and ipsilateral preauricular lymphadenopathy. POGS occurs after direct inoculation of the organisms into the eye. Recently, further ocular features of *Bartonella* infections have been reported. Mainly unilateral neuroretinitis and endophthalmitis with acute visual loss, optic nerve edema, and macular exudates are typical clinical manifestations (Wear et al. 1985; Grando et al. 1999; Dondey et al. 1997; Le et al. 1994; Kerkhoff et al. 1999b; Reed et al. 1998).

NEUROLOGIC MANIFESTATIONS

Neurologic manifestations associated with CSD occur in 2–3 percent of the patients. Encephalopathy, encephalitis, myelitis, radiculitis, and cerebral arteritis are the most frequently reported symptoms. In patients with CSD encephalopathy symptoms usually appear abruptly. Patiens may develop headaches, convulsions, and may become confused and disorientated. Status epilepticus in children has been reported. A history of cat exposure, regional lymphadenopathy, or a papule on the site of inoculation is often missed and is not essential for the diagnosis. Most patients have an abnormal electroencephalogram, but a normal computed tomographic scan of the brain, and mononuclear pleocytosis in the cerebrospinal fluid is found only in 20–30 percent (Carithers and Margileth 1991; Marra 1995; Noah et al. 1995; Easley et al. 1999).

DISSEMINATED CSD

Disseminated CSD has occasionally been described, presenting with a large variety of clinical symptoms and may be difficult to diagnose. Clinical manifestations

include persistent fever (fever of unknown origin (FUO)), hepatic and splenic abscesses, various skin lesions, arthritis, pneumonia, pleural effusion, thrombocytopenic purpura, and osteolytic lesions. Persistent fever, abdominal pain, and vomiting are important symptoms indicating visceral, especially hepatosplenic, involvement (Waldvogel et al. 1994; Dunn et al. 1997; Sander and Frank 1997; Jacobs and Schutze 1998; Arisoy et al. 1999; Robson et al. 1999; Ventura et al. 1999; Ruess et al. 2000).

B. QUINTANA, TRENCH FEVER, AND BACTEREMIA

Trench fever and its etiologic agent *B. quintana* was first described during the First World War. Very soon, Henry da Rocha Lima identified the body louse as the main

vector of transmission of this pathogen. After the First World War, the incidence of trench fever decreased, and the illness reappeared during the Second World War. Thereafter, living conditions improved and *B. quintana* was nearly forgotten for half a century. A reemergence of *B. quintana* infection was observed in recent years in homeless people and chronic alcohol ill patients. The major predisposing factors are living in poor hygienic conditions and infestation with body lice. In 1999, Brouqui et al. reported that 30 percent of homeless people at the University Hospital in Marseille had high antibody titers against *B. quintana*, 14 percent were bacteremic, and 7 percent had persistent bacteremia. *B. quintana* infections among homeless people and in patients with chronic alcoholism were also described in the United States (Jackson and Spach 1996; Spach et al. 1995). Asymptomatic, prolonged bacteremia (up to 78 weeks) or intermittent bacteremia in homeless people may occur. Treatment with gentamicin and doxycycline was effective in preventing relapses of bacteremia (Foucault et al. 2002). Headaches, severe leg pain, and sweats were the main symptoms associated with bacteremia. In homeless people, *B. quintana* might cause acute, severe illness, but chronic infection with few or no symptoms has often been reported.

It was demonstrated that *B. quintana* invades human erythrocytes. However, in infected people, the proportion of infected erythrocytes is very low, ranging between 0.001 to 0.005 percent without signs of anemia. Bacteria may be detected in erythrocytes by confocal microscopy. However, this method lacks sensitivity and the detection limit is about 5×10^4 colony-forming units (cfu) per ml. Infected erythrocytes each may contain up to five bacteria (Rolain et al. 2002).

Nonhemolytic intracellular colonization of erythrocytes is a unique strategy for bacterial persistence. It facilitates efficient transmission by the body lice and protects from host immune responses, as well as antimicrobial therapy.

BACILLARY ANGIOMATOSIS AND PELIOSIS HEPATIS (*B. HENSELAE* AND *B. QUINTANA*)

In immuncompromised, predominantly in human immunodeficiency virus (HIV)-positive patients, infection with *Bartonella* species manifests with vascular proliferative lesions of the skin, known as bacillary angiomatosis (BA). Skin lesions are solitary or multiple (up to 1 000) and are usually red to purple. They develop from small papules to form nodules or tumors which resemble pyogenic granulomas, hemangiomas, or Kaposi's sarcoma. The lesions are occasionally also found in the lymph nodes, liver or spleen, known as bacillary peliosis hepatis, but rarely found in other organs such as bones, brain, and bronchi (Koehler et al. 1992; Koehler and Tappero 1993). Clinical symptoms like fever, chills, night sweats, vomiting, and weight loss are most often reported along with extracutaneous manifestations. HIV-infected patients with BA are severely immunocompromised and the disease is classified as an AIDS-defining opportunistic infection (Mohle-Boetani et al. 1996). The prevalence of *Bartonella* infection among febrile HIV-infected patients was demonstrated to be 18 percent, and should be considered in the differential diagnosis for patients with fever and late-stage HIV disease (Koehler et al. 2003).

Bartonella henselae and *B. quintana* are equally likely to cause cutaneous bacillary angiomatosis. However, there is a strong predilection for *B. henselae* to cause hepatosplenic and lymph node disease (similar to the organs involved in immunocompetent CSD patients), whereas *B. quintana* is more closely associated with osseous and subcutaneous infections (Koehler et al. 1997).

ENDOCARDITIS (MAINLY *B. HENSELAE* AND *B. QUINTANA*)

Blood culture negative endocarditis occurs between 5 and 30 percent of all cases of endocarditis. Recently, *Bartonella* species have been recognized as one of the various causes of blood culture-negative endocarditis. Recent studies have shown that *Bartonella* endocarditis represents 3 percent of all cases of endocarditis (Raoult et al. 1996; Sander et al. 2001a).

In 1993, Spach et al. reported the first case of endocarditis caused by *B. quintana* in an HIV-infected patient, Hadfield el al. (1993) described the first case of endocarditis caused by *B. henselae* and Daly et al. (1993) the first case of *B. elizabethae* endocarditis. Since then, nearly 100 case reports of *Bartonella* endocarditis have been reported in the literature.

Since *Bartonella* spp. are fastidious and very difficult to culture, serologic investigations for antibodies against *Bartonella* sp. might give the first indication of the presence of *Bartonella* endocarditis and should be included in the diagnostic work up of blood culture negative endocarditis. Endocarditis caused by *B. quintana* is mostly reported in homeless and alcoholic patients with no previous cardiac history, whereas *B. henselae* endocarditis is mostly found in patients with previously known valvular heart disease and contact with cats and/or cat fleas (Fournier et al. 2001). The pathologic changes of the heart valves are suggestive of prolonged infection. Compared with other cases of infective endocarditis, cases of *Bartonella* endocarditis are more fibrotic and calcified, less vascularized, with less extensive vegetation and chronic inflammation (Lepidi et al. 2000).

Diagnosis

The diagnosis of CSD is primarily based on clinical examination and should be suspected in cases of regional lymphadenopathy, primary skin lesions, and exposure to cats or cat fleas. The patients are usually in

good general condition and only about two-thirds of them are afebrile.

LABORATORY DIAGNOSIS

Routine laboratory studies do not provide important clues for the diagnosis of CSD. The illness is usually associated with a normal or slightly elevated white blood cell count. The erythrocyte sedimentation rate and the C-reactive protein may be increased. All other routine laboratory tests are usually within normal ranges. In cases complicated with hepatosplenomegalia, liver function tests may show increased concentrations of alkaline phosphatase, aspartate aminotransferase, and γ-glutamyltransferase.

CULTURAL AND BIOCHEMICAL CHARACTERISTICS

Isolation of *B henselae* from lymph nodes of CSD patients has rarely been reported in the literature and seems not to be a reliable method for the diagnosis of CSD. In most studies, cultures of lymph nodes extracted tissue from CSD patients remained sterile. However, a recent study from Australia reported the isolation of *B. henselae* strains from 20.5 percent of 83 PCR-positive human specimens (Fournier et al. 2002b). In contrast, most isolates of *B. henselae* obtained worldwide have been collected from blood cultures of their natural reservoir, the cat. *Bartonella* isolates of human origin are usually obtained from blood and tissue cultures of immunocompromised patients suffering from bacillary angiomatosis or peliosis hepatis.

Since *Bartonella* species may be intracellular and reside within erythrocytes, blood cells lysis by saponin or by freezing improves their recovery. If EDTA-blood tubes are stored frozen at −65°C for several days, recovery of *Bartonella* isolates is even higher than that from the Isolator™ tubes (Brenner et al. 1997). However, using the lysis-centrifugation method (Isolator™ tubes, Wampole, Cranbury, NJ, USA) is more effective than other conventional automated blood culture systems, e.g. Bact/Alert™ (Organon) (Tierno et al. 1995). If conventional blood culture systems are used, blind subcultures on solid media are required, because the organisms produce little or no CO_2 and bacterial growth will not be indicated. In addition, *Bartonella* species can be detected by routine acridine orange staining of aliquots from aerobe bottles after 8 days of incubation (Larson et al. 1994). Acridine orange stain is known to be more sensitive than the Gram stain. Subcultures with prolonged incubation times (up to 4 weeks) on chocolate agar or Columbia agar base are required for isolation of the strains.

Growth of *Bartonella* species on solid media is hemin dependent. *B. henselae* and *B. quintana* grow well on freshly prepared chocolate agar, Columbia blood agar, brain–heart infusion agar, or trypticase soy agar, supplemented with 5–10 percent sheep blood or rabbit blood. Plates should be incubated in a humid atmosphere containing 5–10 percent CO_2 at 35–37°C for at least 4 (to 8) weeks. On solid media, first visible growth does not occur before 6 to 12 days of incubation. Primary colonies may be very heterogeneous, and appear as very small, smooth colonies and/or as rough, irregular, and cauliflower-like colonies. They are whitish-cream and are usually highly adherent and deeply embedded into the agar. Initially, subcultivation might prove difficult and there is a risk of losing the isolate. However, after three to four subpassages, the organisms become adapted, the colonies become smooth and less adherent, and growth occurs within 3–4 days (Sander 2001).

Isolation of organisms from tissue samples may require co-cultivation in cell cultures such as the human endothelial cell line ECV304 described by Drancourt et al. (1995) or a bovine pulmonary artery endothelial cell line detailed by Koehler et al. (1992), before plating on to solid agar media.

Identification of *Bartonella* species in the routine microbiology laboratory might be difficult. All *Bartonella* species are catalase-, oxidase-, indole-, esculin-, and citrate-negative, and they do not produce acid from carbohydrates such as glucose, lactose, maltose, mannitol, sucrose, fructose, inositol, mannose, raffinose, or rhamnose. Conventional biochemical tests are of little use in the differentiation of the organisms and commercially available identification systems do not contain *Bartonella* species in their database. However, anaerobic identifications systems (e.g. RapID ANA II, Rapid ID 32 A, MicroScan rapid anaerobic identification system, An-IDENT System) are shown to be useful for detection of preformed enzyme profiles for *Bartonella* spp. (Regnery et al. 1992a; Clarridge et al. 1995; Sander 1998). Whole-cell fatty acid analysis (CFA) is useful for identification of *Bartonella* strains at the genus level and there are some characteristic amounts of fatty acid compositions for some species (e.g. *B. elizabethae*, *B. bacilliformis*). However, the different *Bartonella* species are not available in the database and differentiation between *B. henseale*, *B. quintana*, and *B. clarridgeiae* by this method is not possible (Clarridge et al. 1995; Sander 1998). Table 5 details the differential characteristics of *Bartonella* species. There are only small differences between *B. henselae* and *B. quintana* in all diagnostic tests available, and these two species can be distinguished from each other only by molecular based methods. *Bartonella clarridgeiae* differs from *B. henselae* and *B. quintana* by the production of β-NAG in the Rapid ID 32 A test (Figure 4).

POLYMERASE CHAIN REACTION AND GENOTYPING

PCR amplification of a *Bartonella* DNA fragment from human specimens is widely used to diagnose *Bartonella* infections. Several different PCR-based assays have been described using primer pairs with different target

genes. However, large differences were found in the sensitivity of these assays, depending on the primers used and on whether fresh (sensitivities ranging from 60 to 100 percent) or formalin-fixed, paraffin-embedded (sensitivities ranging from 43 to 78 percent) tissues were investigated (Sander et al. 1999).

Using a semiquantitative, species-specific PCR enzyme immunoassay, the approximate number of cfu in clinical specimens from patients with CSD or bacillary angiomatosis peliosis (BAP) were calculated to range between 10^3 and 10^6 cfu/ml (Sander and Penno 1999).

A recent study has shown that the results of PCR-based techniques in CSD strongly depend on the duration of disease. *Bartonella henselae* DNA was detected in the extirpated lymph nodes only within the first 6–9 weeks after onset of lymphadenopathy (Ridder et al. 2002). Since CSD lymphadenopathy may last for months, negative PCR results and a positive serology is common in the later stage of the illness.

Based on investigations of different genetic regions, two different genotypes (I and II) of *B. henselae* have been found to be involved in CSD. In different geographic regions, different *B. henselae* genotypes seem to be predominant. In Australia, Germany, and The Netherlands the majority of *B. henselae* isolates from cats belong to genotype II, whereas isolates from humans are mostly identified as genotype I (Fournier et al. 2002b; Sander et al. 1999; Bergmans et al. 1996). In contrast, in Switzerland and France, both cat and human *B. henselae* isolates mainly belong to genotype II (Box et al. 1996; Zeaiter et al. 2002).

However, no differences in the clinical presentation of CSD were found for the different genotypes. In contrast, a recent study suggested that the two *B. henselae* genotypes determined by pulsed field gel electrophoresis (PFGE) may induce different pathological features in HIV-infected patients. Genotype I infected patients were found more likely to have vascular proliferative lesions of the liver and/or spleen than patients with genotype II infections (Chang et al. 2002).

Comparing several different typing techniques for molecular typing of *B. henselae* strains, such as PFGE, repetitive extragenic palindromic (REP)-PCR, enterobacterial repetitive intergenic consensus (ERIC)-PCR, or arbitrary primed (AP)-PCR, PFGE was shown to provide the highest discriminatory potential for subtyping of *B. henselae* strains (Sander et al. 1998b).

SEROLOGY

Until recently, CSD was diagnosed by exclusion or by a positive cat scratch disease skin test reaction. However, this test was never standardized, was not commercially available, and is no longer recommended for the diagnosis of CSD. In the last few years, reliable serological tests and molecular based methods have been established worldwide.

Serological testing for *Bartonella* antibodies should be the first step in the diagnosis of typical and atypical CSD and in suspected *Bartonella* endocarditis. A primary negative serological test result does not necessarily exclude a current infection. In some patients, seroconversion may not occur until 3 weeks after onset of disease (Dalton et al. 1995).

Different serological methods, e.g. indirect fluorescence assay (IFA), enzyme immunosorbent assay (EIA), and Western blot have been established for the diagnosis of *Bartonella* infections. The antigen preparation seems to be essential for these tests and antigen extracted from plate-grown *Bartonella* species may lead to false negative results.

IFA is currently the most common test used. It is commercially available and based on antigens prepared from organisms co-cultivated in cell cultures (e.g. Vero cells, human endothelial cell line ECV 304). Comparing different indirect fluorescence assays (e.g. slides from BION Enterprises, Park Ridge Chicago, IL, USA; Focus Technologies (formerly MRL Diagnostic), Cypress, CA, USA; or in-house slides) it was shown that the commercial slides are higly sensitive (85–100 percent), but less specific (73–87 percent) (Maurin et al. 2002; Sander et al. 1998a; Zbinden et al. 1997). Slides for specific detection of *B. henselae* and *B. quintana* are available. However, many studies have demonstrated that serological differentiation between *B. henselae* and *B. quintana* infections is definitely not possible, due to the very high cross-reactivity between both species (95–100 percent). In some cases, titers against *B. quintana* are even higher than those against *B. henselae* in proven *B. henselae* infections (Dalton et al., 1995; La Scola and Raoult 1996; Sander et al. 1998a; Maurin et al. 2002). Similar results have been reported for proven *B. quintana* infections, where 68 percent of patients exhibited higher titers of antibodies to *B. henselae* than to *B. quintana* (Fournier et al. 2002a).

The prevalence of antibodies to *B. henselae* is very high in particular geographic regions. Up to 30 percent of the adult population has detectable IgG antibodies (titers of 1:64 to 1:256) in Europe and no differences between cat owners have been reported (Rath et al. 1997; Zbinden et al. 1997; Sander et al. 1998a). In the United States the seroprevalence in the general population is reported to be 4–6 percent (Zangwill et al. 1993), but healthy family members of patients with CSD may be seropositive in about 30 percent of cases (Demers et al. 1995). Finally, the prevalence of antibodies to *Bartonella* depends on the age of the individuals investigated. A lower seroprevalence of 3.5–13 percent (depending on the test used) was found in children (Sander et al. 2001b).

Due to the high seroprevalence in the general population, the diagnosis of CSD may be difficult in some cases. In general, IFA titers of <1:64 suggest that the patient does not have a current *Bartonella* infection. IgG

antibodies in CSD patients are usually high (⩾1:512), whereas low antibody titers between 1:64 and 1:256 are found not only in CSD patients, but also in up to 30 percent of healthy controls. Therefore, low antibody titers might indicate the beginning or the end of CSD, but may also indicate only prior exposure to *Bartonella* spp. In such cases, a titer increase in a second serum sample (collected 2–3 weeks later) may confirm the diagnosis. Only seroconversion, high IgG titres of ⩾1:512, or a four-fold titer increase in a second serum sample are indicative of CSD. Specific IgM antibodies are less frequently detected in CSD patients and lack of IgM does not exclude a *Bartonella* infection (for a review see Sander et al. 2001b). *Bartonella* endocarditis usually evokes high IgG antibody titers (>1:800). Thus, in cases of culture negative endocarditis high antibody titers may therefore be considered diagnostic (Fournier et al. 2002a).

Western blot analysis and enzyme-linked immunoassays have been described for diagnosis of *Bartonella* infections. Based on whole cell antigen of *B. henselae*, both tests lack sensitivity and specificity, and cross-reactions with different other bacterial infections have been described (*Ehrlichia chaffeensis*, *Mycoplasma pneumoniae*, *Escherichia coli*, *Francisella tularensis*, *Treponema pallidum*, *Chlamydia* spp., *Coxiella burnetii*, and *Rickettsia rickettsii*) (McGill et al. 1998; La Scola and Raoult 1996; Maurin et al. 1997). Western blotting and crossadsorption of the sera with *B. henselae*- and *B. quintana*-antigen suspensions (shaken for 24 h at 4°C) was described to allow identification of the *Bartonella* species in cases of infective endocarditis on a serological basis (Houpikian and Raoult 2003).

Under circumstances where serological testing and the clinical presentation of the patient do not clearly indicate the diagnosis of CSD, fine needle aspiration or surgical removal of the lymph node for histopathological and molecular-based diagnostic procedures is strongly recommended to rule out more severe diseases such as lymphoma or mycobacterial infection. Using a monoclonal antibody against *B. henselae*, which reacts with a *B. henselae* specific 43-kDa epitope, the CSD agent was recently detected by immunofluorescence in lymph node smears of CSD patients (Rolain et al. 2003).

HISTOPATHOLOGY

Histopathological examination of the lymph nodes from patients with CSD shows three evolutionary stages: (1) enlargement of the lymph node caused by the expansion of the cortex and hyperplasia of the germinal centers with epithelioid granulomas and Langhans' giant cells; (2) enlarged granulomas, which become infiltrated with polymorphonuclear leukocytes developing central necrosis with progressive suppuration; and (3) development of pus-filled sinuses and rupture of the capsule may occur. The histopathological presentation of CSD is very similar to those of other granulomatous diseases, e.g. sarcoidosis, infectious mononucleosis, mycobacterial infections, lymphogranuloma venereum, brucellosis or tularemia (Kaschula 1996). Detection of specific bacterial DNA by PCR in any biopsy specimens and serological investigations may be helpful to avoid misdiagnosis in such cases.

Histological findings of BA consist of tumor-like capillary proliferations with plump endothelial cells that protrude into the vascular lumen. These changes are very similar to those seen in verruga peruana and may resemble lesions from Kaposi's sarcoma, pyogenic granuloma, epithelioid hemangioma, and angiosarcoma.

Detection of the *Bartonella* bacilli by Warthin–Starry silver staining of fixed tissue sections in patients with CSD during the early stages of lymphadenopathy was demonstrated, but not in the later granulomatous stage of the illness. In a study performed by Demers et al. (1995), *Bartonella* bacilli were found by this method in only 12.5 percent (four of 32) of patients with CSD and in four of seven patients with BA (Gasquet et al. 1998). In a study performed by Fournier et al. (2002a) argyrophilic organisms have been detected by Warthin–Starry staining in 50 percent of PCR-positive lymph nodes.

In summary, detection of *Bartonella* spp. by culture (extremely unreliable), by Warthin–Starry staining (very insensitive), as well as detection of *Bartonella* DNA by PCR (highly specific, sensitivity depends on the duration of illness) in lymph nodes of patients with CSD seems to be successful only in the first weeks of lymphadenopathy. The early disappearance of the bacteria in the enlarged, persistent lymph nodes, illustrate the importance of highly sensitive and specific serologic methods in the diagnosis of CSD. In more severe and atypical cases, other diseases (e.g. lymphoma) should be excluded by histological examination of the lymph nodes and/or by other additional tests.

Treatment and susceptibility to antimicrobial agents

In vitro, all *Bartonella* isolates were highly susceptible to most antibiotics tested, including macrolides, tetracyclines, aminoglycosides, fluoroquinolones, β-lactams (penicillin G, aminopenicillins, third-generation cephalosporins), trimethoprim-sulfamethoxazole, and rifampin. Vancomycin, which is known to be effective against gram-positive bacteria, shows minimum inhibitory concentration (MIC) close to the breakpoint of 4 mg/l. However, in vivo, treatment of *B. henselae* or *B. quintana* infections may be difficult. Penicillins and first-generation cephalosporins are not effective.

Cat-scratch disease is a self-limiting disease and the effectivity of antimicrobial therapy remains unclear.

In cases of typical CSD, antibiotic therapy is usually not indicated. Antibiotic treatment should be considered in patients with prolonged fever and severe systemic symptoms (usually atypical CSD). Macrolides (erythromycin, azithromycin), tetracyclines, rifampin, and in some cases ciprofloxacin, have been shown to be effective and are considered as the drug of choice for the treatment of CSD. Unfortunately, only one prospective, randomized, double-blind and placebo-controlled study on the treatment of CSD is reported (Bass et al. 1998). Oral azithromycin taken for 5 days (500 mg in the first day, and 250 mg on days 2–5) was shown to be effective (decrease in the size of the lymph node) within the first 4 weeks of treatment. However, new enlarged lymph nodes or lymph nodes increazing in size may appear despite therapy. In both the azithromycin-treated and the placebo-treated group, the lymph nodes disappeared within 4 months.

In contrast to CSD, antimicrobial therapy in immunocompromised patients is absolutely indicated. In patients suffering from BA or peliosis hepatis, erythromycin at a dose of 250–500 mg, four times/day is considered the drug of choice. Newer macrolides and tetracyclines are also effective. The duration of treatment should be at least 2 months, in some cases even longer (Spach and Koehler 1998).

In patients suffering form *Bartonella* endocarditis, surgical valve replacement could not be prevented in most cases despite antbiotic treatment.

Pathogenesis

Bartonella infections are vector-borne diseases. Many species were shown to multiply and persist in red blood cells of their natural hosts. *Bartonella henselae* was found in red blood cells of cats (Kordick and Breitschwerdt 1995; Rolain et al. 2001), *B. tribocorum* in those of rats (Schülein et al. 2001), and *B. quintana* (Rolain et al. 2002) and *B. bacilliformis* (Benson et al. 1986) were shown to invade human erythrocytes. The ability of *Bartonella* to persist in erythrocytes for long periods increases its transmissibility by blood sucking arthropods (cat flea, human body louse, sandfly). On solid media, growth of *Bartonella* species is strongly hemin dependent. For *B. henselae* it was shown that the bacteria are unable to synthesize heme itself. The heme precursor protoporphyrin IX alone, or in combination with $FeCl_2$ or $FeCl_3$, as well as transferrin or lactoferrin, do not support growth (Sander et al. 2000b). A large number of different outer membrane proteins involved in the utilization of heme compounds are known. Recently, Carroll et al. (2000) detected nine different outer membrane hemin-binding proteins from *B. quintana* by hemin blots, including a 30-kDa protein, which showed a close homology to the phage-associated membrane protein Pap31 of *B. henselae* (Bowers et al. 1998). It was demonstrated that the *pap31* gene of *B. henselae* was necessary and sufficient to restore growth of a heme-deficient mutant of *E. coli* (Zimmermann et al. 2003). Pap31 seems to be one of the hemin-binding proteins involved in heme acquisition and may be an important virulence factor in this human pathogen.

A second typical pathogenic feature of *Bartonella* spp. is the ability to induce endothelial cell proliferation and to trigger neoangiogenesis, as observed in bacillary angiomatosis (*B. henselae* and *B. quintana*) and verruga peruana (*B. bacilliformis*). *Bartonella* sp. can provoke angioproliferation by at least two independent mechanisms: directly by triggering proliferation and inhibiting apoptosis of endothelial cells; and indirectly, by stimulating the infected host cells to produce VEGF, the angiogenic vascular endothelial growth factor (Kempf et al. 2001; Schweyer and Fayyazi 2002; Kirby and Nekorchuk 2002; Dehio 2003).

Endothelial interactions involve a unique mode of cellular invasion, the activation of proinflammatory responses and the formation of vasoproliferative tumors (Dehio 2001). *Bartonella*–endothelial cell interaction is not restricted to angiogenesis stimulation. Invasion of endothelial cells was shown for *B. quintana*, *B. henselae*, and *B. bacilliformis* and a proinflammatory activation of endothelial cells was postulated to be a result of receptor–ligand interactions between the activated endothelium and circulating neutrophils (Greub and Raoult 2002). Further research is needed to elucidate the interactions between these pathogens with erythrocytes and endothelial cells.

INFECTIONS CAUSED BY OTHER *BARTONELLA* SPECIES

Bartonella henselae, *B. quintana*, and *B. bacilliformis* are the most common *Bartonella* species associated with human diseases. In recent years, further *Bartonella* species were reported to be pathogenic to humans, most of them isolated from blood cultures of patients suffering from cardiac diseases.

Bartonella elizabethae was first described in 1993 by Daly et al. (1993) and was isolated from a 31-year-old man with fever (39°C) and endocarditis. He reported a 2-month history of fatigue, malaise, anorexia, and shortness of breath accompanied by a weight loss of 9 kg. A two-dimensional echocardiogram revealed large vegetations on the aortic valve and severe aortic regurgitation. Despite therapy with intravenous nafcillin and gentamicin, and lack of fever after 48 h of therapy, he developed increasing congestive heart failure and the aortic valve had to be replaced surgically.

A second case report with serologic evidence (titer 1:128) of a *B. elizabethae* infection was presented in 1998 by O'Halloran et al. from a patient suffering form Leber's neuroretinitis.

Two recent case reports implicated *Bartonella clarridgeiae* as another possible agent of CSD. Based solely on the detection of antibodies, Kordick et al. (1997)

presented the first report of CSD supposed to be caused by *B. clarridgeiae*. A veterinarian was bitten by a kitten and presented symptoms similar to CSD. Initial cultures from the patient and the cat were negative. *Bartonella clarridgeiae* was isolated from the blood of the cat at 1.5 months and again at 4 months after the initial event. The patient developed fever, headache, and lymphadenopathy within 3 weeks of the bite. He did not seroconvert to *B. henselae*, *B. quintana*, or *B. elizabethae* antigens, but demonstrated a reciprocal titer of 1024 against the *B. clarridgeiae* cat isolate.

The second case was presented by Margileth and Baehren (1998). The authors describe a patient with an extensive axillary and chest-wall abscess and the diagnosis based on a seroreactivity only to *B. clarridgeiae*, at a titer of 1:128. However, a culture of the drainage yielded *Streptococcus pneumoniae*. Unfortunately, no molecular based diagnostic tests were applied to confirm the presence of *B. clarridgeiae* DNA in the abscess mass and a possible role of the isolated *S. pneumoniae* in the etiology of this abscess cannot be ignored.

Lack of information on the seroepidemiology of *B. clarridgeiae* complicates an assessment of the organism's true role in infection. Up to now, no culture-proven, or at least PCR-proven, *B. clarridgeiae* infection in humans has been reported and serologic crossreaction between *B. henselae* and *B. clarridgeiae* is seen by IFA. In contrast to *B. henselae*, *B. clarridgeiae* is flagellated. Based on the 41-kDA FlaA protein, an immunoblot was developed and antibodies against this protein were detected in 3.9 percent of patients suffering from lymphadenopathy (Sander et al. 2000a). However, whether antibodies to the FlaA protein of *B. clarridgeiae* are a useful indicator of acute infection remains to be clarified. Future studies are needed to define this organism better as the causative agent of CSD.

Bartonella grahamii was recently detected by PCR analysis from the intraocular fluid of a 55-year-old HIV-negative patient suffering from bilateral neuroretinitis and behavioral changes. The patient was successfully treated with doxycycline (200 mg/day) and rifampin (600 mg/day) for 4 weeks (Kerkhoff et al. 1999a).

B. vinsonii subsp. *berkhoffii* is known to cause bacteremia and endocarditis in dogs. In 2000, Roux et al. described a 35-year-old male patient with a history of feeling unwell for a month, shortness of breath, and chest pain for a week. The patient had both a cat and a dog and was exposed to several other animals. C-reactive protein and erythrocyte sedimentation rate were elevated. Transthoracic echocardiography showed a dilated left ventricle and a bicuspid aortic valve with thickened cusps and significant regurgitation. The patient was afebrile, all blood cultures collected were negative, and no antibiotics were administered. After 3 weeks the patient underwent an aortic valve replacement and *B. vinsonii* subsp. *berkhoffii* was detected by PCR. Anti-*Bartonella* antibodies against *B. henselae* were 1:200, against *B. quintana* 1:400, and against *B. vinsonii* subsp. *vinsonii* 1:100.

Bartonella vinsonii subsp. *arupensis* was isolated in 1994 from the blood culture of a 62-year-old Caucasian cattle rancher from Wyoming, presenting with acute onset of fever (38.3°C), bacteremia, and a relapse of the vasculitis and the associated neurologic manifestations of his Sjögren's syndrome, diagnosed in 1960 (Welch et al. 1999).

Bartonella washoensis was first isolated in 1995 by Regnery from the blood culture of a 70-year-old male resident of Washoe Country, Nevada, who developed fever and myocarditis. The sequences of three genes of this novel species were submitted to GenBank in 1998 and in 2003 the same species was isolated from a California ground squirrel, suggesting that these animals may serve as a reservoir for human infections (Kosoy et al. 2003).

In recent years the recognized diseases caused by *Bartonella* spp. increased continuously. As more laboratories are engaged in the study of these organisms, the spectrum of disease will continue to expand.

AFIPIA

THE GENUS *AFIPIA*

Epidemiology and clinical significance

Detection of *Afipia* species from human specimens is extremely rare and was initially related to CSD. In 1988, *Afipia felis* was first isolated from the lymph nodes of ten patients suffering from CSD (English et al. 1988). Three additional isolates of *A. felis* have been cultured from lymph node aspirates of two children by Brenner et al. (1991). The same authors described two other *Afipia* species (*A. clevelandensis* and *A. broomeae*), as well as three unnamed *Afipia* genospecies (1, 2, and 3). The name *Afipia* is derived from the acronym AFIP, for Armed Forces Institute of Pathology, where the type species was isolated. A further isolate of *Afipia felis* was cultured from a lymph node of a CSD patient in 1998 by Giladi et al. However, in the same study 32 lymph node specimens of CSD patients tested positive for *B. henselae* by PCR, but negative for *A. felis*.

Indirect evidence suggests that *A. felis* may indeed be associated with some human infections. Drancourt et al. (1992) reported a patient with acute meningoencephalitis who seroconverted to positivity for *A. felis* antibodies. Antibodies against *A. felis* have been demonstrated in 17 percent of CSD patients (Fumarola et al. 1994). However, Amerein et al. (1996) found no differences in *A. felis* antibody titers among CSD patients and controls.

Since the first description of *A. felis*, a large number of serological, molecular based, and cultural methods demonstrated that *B. henselae* and not *A. felis* is the main etiologic agent of CSD worldwide. Additionally, there is

Afipia felis genospecies A (CIP 106335)	Water supply of a hospital	La Scola et al. (2000, 2002)

ATCC, American Type Culture Collection; CIP, Collection de l'Institut Pasteur, Paris, France.
Modified after Brenner et al. 1991 and La Scola et al. 2002

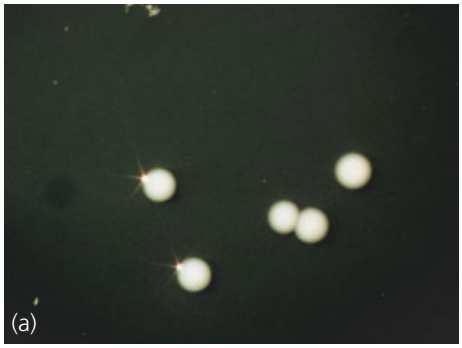
no evidence indicating that cats represent a reservoir for *A. felis* as they do for *B. henselae*. Therefore, the term 'cat-scratch-disease' should be reserved for infections caused by agents which indeed are transmitted by cats.

The natural reservoir for *A. felis* was unknown for a long time. Recently, successfully isolation of *A. felis* and other *Afipia* species from hospital water in an amoebae co-culture procedure was reported (La Scola and Raoult, 1999; La Scola et al. 2002). Therefore, it cannot be excluded that the reported isolation of *A. felis* from lymph nodes in the three institutions might have been caused by water contamination. However, the clinical relevance of *Afipia* species remains to be further elucidated, and hospital-aquired infections might occur. These organisms may play a role as opportunistic pathogens in respiratory and wound infections in elderly patients and in those with severe underlying medical problems. The currently described *Afipia* species are presented in Table 6.

Cultural and biochemical characteristics

Members of the genus *Afipia* belong to the α-2 subgroup of the Proteobacteria and are gram-negative, oxidase-positive, urease-positive, weakly catalase-positive rods. *Afipia* species have been shown to have similar axenic growth requirements to *Legionella* species and co-culture studies demonstrated that *A. felis* has the ability to grow associated with amebae, indicating that they may exist in aquatic environments (La Scola et al. 2000).

Afipia species appear to be relatively fastidious and difficult to cultivate in the routine laboratory. Original reports on isolation of *A. felis* described successful growth using ground lymph node tissue in brain–heart infusion broth and on brain–heart infusion agar (BHIA) (English et al. 1988; Giladi et al. 1998). In primary cultures, visible growth occurs after 1–2 weeks of incubation at 30–32°C without CO_2. Subcultures should be performed on BHIA or on buffered charcoal yeast extract agar (BCYE) and after several passages, the time to detection of growth is reduced to 3–5 days. *A. clevelandensis* has been recovered on chocolate blood agar at 35°C and on brain–heart infusion agar with blood and potato dextrose agar at 25°C (Hall et al. 1991). Colonies of *Afipia* sp. are gray-white, shiny, convex, opaque with entire edges, measuring 0.5–1.5 mm in width (Figure 5a).



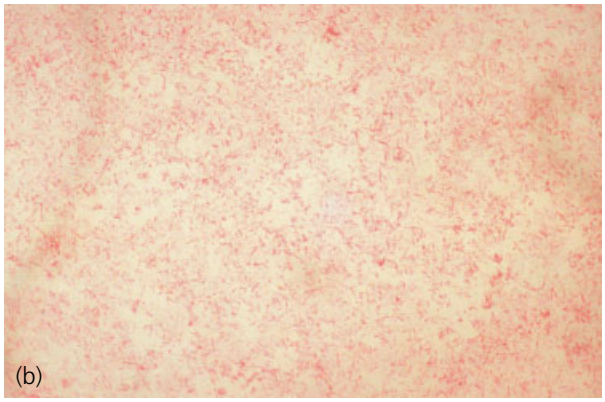


Figure 5 (a) A. felis *colonies grown on BCYE agar for 7 days at 30°C.* **(b)** *Microscopic morphology of Gram-stained* A. felis.

a) Incubation at 30°C unless indicated otherwise.
b) Heavy inoculation.
Adapted from Brenner et al. 1991 and La Scola et al. 2002

Additional isolates of *A. felis* have been recovered using a tissue culture system. Sonicated fluid and tissue specimens added to HeLa cell monolayers incubated for up to 18 h at 35°C with subsequent passage on to secondary cell monolayers and on to buffered charcoal yeast extract agar have yielded growth (Brenner et al. 1991; Birkness et al. 1992). It was shown that *Afipia felis* induces uptake by macrophages directly into a non-endocytic compartment and the mechanism of intracellular survival of *A. felis* is due to a phagosome–lysosome inhibiting factor (Brouqui and Raoult 1993; Lührmann et al. 2001).

Microscopically, the organisms vary in staining characteristics from relatively uniform gram-negative rods to pleomorphic slender gram-negative rods with vacuoles. In broth cultures, on prolonged incubation for 3 weeks at 37°C, *A. felis* may demonstrate delicate pleomorphic forms (English et al. 1988) consistent with cell wall-deficient organisms. Giladi et al. (1998) describe the Gram-staining characteristic of their isolate as a small, thin, curved gram-negative bacillus when taken from 5-day-old growth (Figure 5b).

All *Afipia* strains are nonhemolytic and grow at 25–30°C. Restricted growth occurs at 35°C, but strains fail to grow at 42°C or on media containing 6 percent NaCl. With the exception of *A. birgiae*, all strains were motile by means of a single polar or subpolar flagellum.

The biochemical reactions that allow differentiation between the species are given in Table 7. Biochemical tests can be performed by inoculation of API 20NE and API 50CH strips (bioMérieux) according to the manufacturer's instructions, followed by incubation at 30°C for 7–15 days. Strains are negative for hemolysis, arginine dihydrolase activity, esculin and gelatin hydrolysis, β-galactosidase activity, H_2S production and acid production of most carbon substrates, including glucose, fructose, mannose, sucrose, mannitol, and maltose. The G + C content of *Afipia* species varies from 59.3 to 69.0 mol% (Brenner et al., 1991; La Scola et al. 2002).

The profiles of the whole-cell wall fatty acid compositions of members of the genus *Afipia* showed that all strains shared relatively large amounts of hexadecanoic acid ($C_{16:0}$), *cis*-octadec-9-enoic acid ($C_{18:1\omega7c}$), and octadecanoic acid ($C_{18:0}$). With the exception of *A. birgiae*, all strains contained *cis*-hexadec-9-enoic acid ($C_{16:1\omega7c}$) (Brenner et al. 1991; La Scola et al. 2002).

Antimicrobial susceptibility

No standards exist for testing and interpreting in vitro susceptibility data for *Afipia* species and no detailed therapeutic clinical efficacy exists during treatment for putative infections with these organisms.

In vitro testing of *Afipia* strains using the microbroth dilution test method in nutrient broth with an inoculum of 1×10^5–5×10^5 cfu/ml (plates were incubated at 30°C and read 72–96 h later) revealed a high susceptibility to imipenem, aminoglycosides, and rifampin, but intermediate susceptibility or resistance to penicillins, cephalosporines, ciprofloxacin, doxycycline, and cotrimoxazole. Great differences concerning the MICs have been observed among the different species, the most resistant strain seems to be *Afipia* genospecies 1 (La Scola et al. 2002). Brenner and colleagues (1991) used the Sceptor system (Becton Dickinson Microbiology Systems, Cockeysville, MD, USA) incubated at 30°C for 48 h to determine specific minimal inhibitory concentrations for all *Afipia* species. Their data demonstrate *Afipia* genospecies 3 to have the lowest MICs among all strains tested. Other species showed higher MICs to most of the antimicrobial agents tested, including first-, second-, and third-generation cephalosporins, ampicillin, and extended spectrum penicillins, β-lactamase inhibitor combinations, aminoglycosides, and tetracycline. The lowest MICs for all species were with imipenem.

Spirillum minus and *Streptobacillus moniliformis*

SCOTT A. MARTIN

Spirillum minus	1	Conclusion	4
Streptobacillus moniliformis	2	References	5

SPIRILLUM MINUS

Definition

Morphologically this organism is motile and spiral-shaped, but its uncertain taxonomic placement is likely to remain so until appropriate nucleic acid phylogenetic studies can be performed. The likelihood of such studies is uncertain because the organism has not been grown in pure culture. *Spirillum minus* is the etiological agent of rat-bite fever or Sodoku (Hitzig and Liebesman 1944; Roughgarden 1965). This infectious disease is transmitted in the secretions of the mouth or nose or urine of an infected rodent, most commonly via a rat bite.

Introduction and historical perspective

Carter, in 1888, was apparently the first to describe what he termed *Spirillum minor* in wet mounts prepared from the blood of a wild rat. The specific epithet 'minor' is grammatically incorrect and was subsequently changed to *S. minus* (Robertson 1924). This spirillum was initially described as being a rigid cell with two or three spiral turns or planar waves. The cells have blunt or pointed ends, a cell length of 0.8–5 μm, a diameter of approximately 0.2 μm, and a wavelength of 0.8–1.0 μm. The cells are actively motile with bipolar flagella. *S. minus* had been isolated from the blood of infected patients in blood culture medium, but efforts to subculture on solid medium have failed (Roughgarden 1965). The history of this bacterium and its disease is further complicated because rat-bite fever is also known to be caused by *Streptobacillus moniliformis* (Brown and Nunemaker 1942).

Habitat

The principal reservoir of *S. minus* is the rat. Other reservoirs or carriers of the bacterium may be mice, guinea pigs, squirrels, weasels, gerbils, wild and domestic cats, and possibly other carnivores. In infected rats the organism is consistently demonstrated in blood and peritoneal fluid, the conjunctival fluid, and muscles of the tongue. The latter two foci obviously figure prominently in transmission of the spirilla to the bite victim. Carrier rats and mice may occasionally show eye infections (Manouelian 1940). Carrier rates of *S. minus* among rats vary widely, from 0 percent in Atlanta, GA, USA, to 25 percent in London, UK, where serous fluid and blood of trapped rats were examined for the bacterium (Biberstein 1975; McHugh et al. 1985).

Staining reactions and culturability

S. minus is readily stained by aniline stains such as Giemsa's or Wright's stains and Loeffler's methylene blue. The Gram reaction of *S. minus* is not stated in Bergey's *Manual of determinative bacteriology* (Holt et al. 1994). Hitzig and Liebesman (1944) described in detail their investigation of a case of subacute bacterial endocarditis caused by *S. minus*. They described their successful efforts to cultivate *S. minus* from blood of this

patient in two different veal infusion broths in a CO_2 extinction candle-jar and the bacterium was maintained in this environment for 11 months. Microscopic examination of Gram stains of the veal infusion broth cultures showed gram-negative and gram-positive spiral-shaped organisms. These results suggest that *S. minus* is gram-variable. Others have tried to repeat this work. Although successful primary isolations have been reported (Roughgarden 1965), the successful long-term in vitro subcultivations of *S. minus* on solid media and its Gram reaction remain unsolved. A similar lack of data obviously applies to growth requirements, metabolism, pathogenicity, antigenicity, and genetic mechanisms.

Antibiotic susceptibility

In vivo, antimicrobial susceptibility studies stem largely from empirical efficacy studies with penicillin, tetracycline, chloramphenicol, and streptomycin given to experimentally infected mice (Roughgarden 1965). Although these studies were done primarily to determine therapeutic efficacy, they also served to establish a spectrum of antibiotic susceptibility that is still accepted today.

STREPTOBACILLUS MONILIFORMIS

Definition

Streptobacillus moniliformis is a fastidious, highly pleomorphic, aerobic and facultatively anaerobic, gram-negative rod with characteristic yeast-like swellings that readily give rise to L-phase and transitional variants. The organism ferments a range of carbohydrates: it is catalase-negative, oxidase-negative, indole-negative, and urease-negative. The bacillus causes a type of rat-bite fever and is responsible for outbreaks of Haverhill fever. The guanine and cytosine (G+C) content of the DNA is 24 to 26 mol%.

Classification

Currently there is only one species in the genus *Streptobacillus* and the taxonomic position of *S. moniliformis* is uncertain. It appears to have properties more in common with the Mycoplasmatales (Costas and Owen 1987).

Introduction

S. moniliformis, isolated by Levaditi et al. (1925) from the blood of a laboratory worker, is now considered the same organism as *Streptomyces muris ratti* (Schottmuller 1914; Tunnicliff 1916). It is similar to *Haverhillia multiforme* (Parker and Hudson 1926) although the two organisms have not been directly compared. Over the years various synonyms have been associated with this organism (Brown and Nunemaker 1942).

Klieneberger (1935) found that colonies of *S. moniliformis* consisted of two elements: the streptobacillary form and what she took to be a mycoplasma, which she named L-form or L_1. Even though the L_1 appeared not to revert to the streptobacillary form (Klieneberger 1942), it is now regarded as an L-phase variant.

Habitat

The bacterium occurs worldwide as a commensal of the nasopharynx of healthy laboratory rats (Strangeways 1933) and wild rats, sometimes being excreted in the urine. It is also isolated from the nasopharynx of diseased mice and from other rodents.

Morphology

It is a gram-negative, highly pleomorphic bacterium that generally occurs as short coccobacillary forms or rods, appoximately 0.5 μm in width, as well as chains and intertwining wavy filaments (Figure 1a). The filaments may show spherical, oval, or club-shaped gram-variable swellings up to 3 μm in diameter and may give rise to a 'string-of-beads' appearance – hence the description '*moniliformis*' (Latin *monile*, necklace; *forma*, shape or form). In aging cultures, filaments show degenerative changes with the formation of granules and extracellular droplets, irregularity or failure of staining, and fragmentation. In broth medium and in vivo, pleomorphism is less pronounced. The organism is nonmotile. In general, older cultures may not stain well with the Gram stain; Giemsa or Wayson stain may yield better results (Piot 1991).

Culture characteristics and growth requirements

On serum or blood agar it forms circular, translucent colonies with a smooth glistening surface. It is nonhemolytic. Smaller, rougher 'transitional' colonies may be present, and in older cultures mutant L-phase colonies may be recognizable, with their typical 'fried-egg' appearance; these are best seen on a clear medium (Cohen et al. 1968). Blood, serum, ascitic fluid, or synovial fluid, is required for growth. It may appear to be an obligate anaerobe on primary isolation, but it is a facultative anaerobe on subculture. Optimum growth is probably best achieved on chocolate–blood agar or tryptose soy agar, both enriched with 10–20 percent serum and incubated in a microaerophilic atmosphere with additional CO_2 and humidification. Basal medium containing 15 percent sterile defibrinated rabbit blood supports the

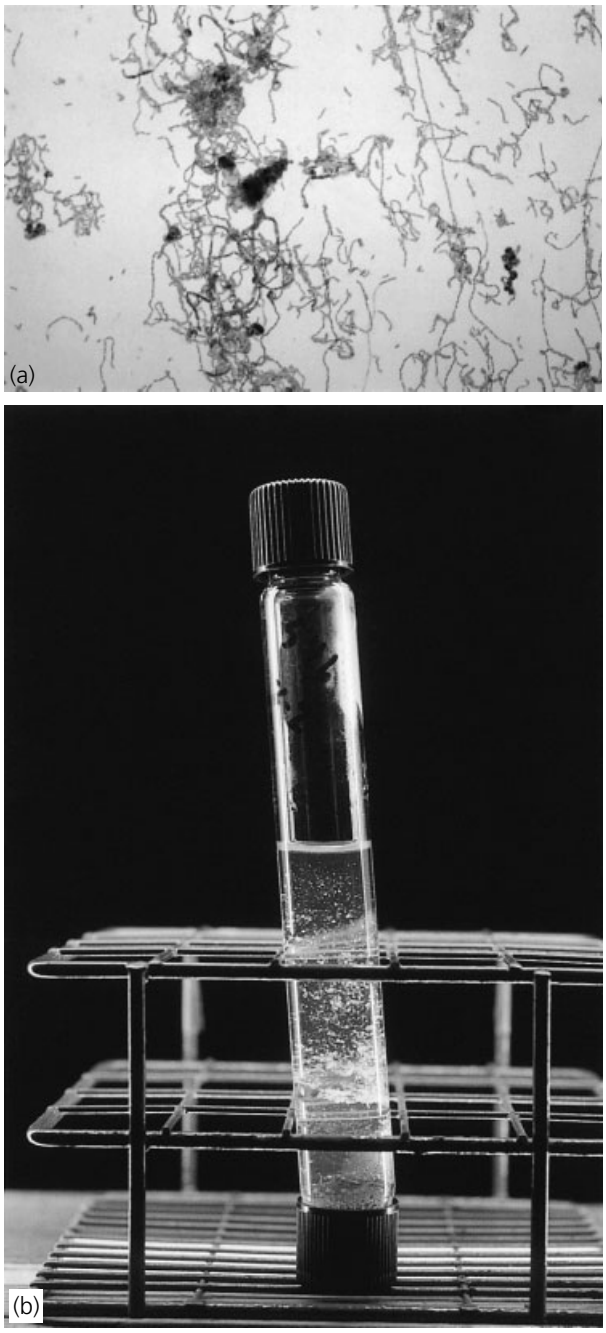

Figure 1 (a) *Typical bacilli (some in chains) and filaments with bulbous swellings (oil immersion; original magnification ×1 000).* **(b)** *Thioglycolate broth with 'puff-ball' colonies. Reproduced with permission from Graves and Janda (2001)*

bacterial-phase organisms well, whereas a clear medium will enhance the isolation of the more nutritionally fastidious L-phase variants (Jenkins 1988). The optimal temperature for growth is 35–37°C, optimal pH 7.4–7.6. The choice of a fluid blood-culture medium is critical: Shanson et al. (1985) recommend brain–heart infusion broth with 0.05 percent cysteine and 2.5 percent Panmede. This could be used in conjunction with a suitable L-phase fluid medium.

Metabolism

The organism is generally nonreactive, with negative reactions for catalase, oxidase, indole production, nitrate reduction, and urease (Table 1). It attacks sugars fermentatively; acid is produced from glucose (without gas), galactose, glycogen, dextrin, raffinose, and starch and variably from fructose, maltose, mannose, salicin, lactose, sucrose, trehalose, and xylose, depending on the basal medium employed. Acid is not formed from sorbitol or mannitol.

The alkaline phosphatase reaction is positive. The end products of glucose metabolism consist mainly of lactic acid with some succinic acid.

Cell-wall and envelope composition; antigenic structure

The major long-chain fatty acids are C(16:0), C(18:2), C(18:1), and C(18:0) (Rowbotham 1983). The electrophoretic profiles of cellular proteins are characteristic and can be used to type strains, 'Haverhill fever' strains being distinguishable from 'rat-bite fever' strains (Costas and Owen 1987).

Strains are antigenically homogeneous, but L-phase variants lack an antigen present in the bacillary form. The species can be identified by fluorescence with a conjugated specific antiserum.

Pathogenicity and virulence factors

Streptobacillary rat-bite fever occurs worldwide and may occur following the bite of a rat or occasionally a mouse, squirrel, weasel, dog, or cat. Most human infections probably occur in children sleeping in rat-infested dwellings. Infections among rodent handlers, laboratory workers, as well as rodent pet owners also occur (Berger et al. 2001). The incubation period is usually 1–4 days and rarely more than 10 days. Onset is typically abrupt with fever, headache, vomiting, and migratory arthralgias and myalgias (Hudsmith et al. 2001). At the time of presentation, the bite wound has generally healed and regional lymphadenopathy is typically not noted. Within 2–4 days after onset, a rash develops over the palms, soles, and extremities. It may present as maculopapular, petechial, or pustular. Symptoms generally resolve over the period of 2 weeks.

Haverhill fever, or erythema arthriticum, is a form of streptobacillary fever that occurs in outbreaks, with vomiting and pharyngitis as prominent symptoms. It appears not to be attributable to direct contact with animals. It was named after Haverhill, Massachusetts, where the first recorded epidemic of the disease occurred (Parker and Hudson 1926); this was thought to be associated with the consumption of raw milk and milk products. The first outbreak in the UK (Shanson et al. 1983) affected pupils and staff of a boarding school in Essex. Of some 700 people exposed, 304 (43 percent) became ill in a period of 10 days (McEvoy et al. 1987).

Adult rats are generally resistant to experimental infection, although newborn rats may develop pneumonia (Strangeways 1933). Mice given the organism intravenously develop either a rapidly fatal septicemia or arthropathy of the lower limbs, with longer survival, the severity of the condition being dose-related (Savage et al. 1981).

Laboratory isolation and identification

Streptobacillary rat-bite fever is usually diagnosed by the isolation of *S. moniliformis* from blood, joint fluid, or pus. If isolation is unexpected, the organism may not be readily identified. Clinically similar conditions such as tularaemia, leptospirosis, rickettsia, and various viral infections should be ruled out. If streptobacillary fever is suspected and routine laboratory cultures are negative, the organism may sometimes be isolated by intraperitoneal inoculation of infected material into mice. Because of the fastidious nature and the slow growth of these gram-negative facultative anaerobic rods and the strict growth requirements, including special media that are not readily available, the diagnosis of streptobacillary rat-bite fever is difficult (Berger et al. 2001).

An enzyme-linked immunosorbent assay (ELISA) for monitoring rodent colonies for *S. moniliformis* has been described by Boot et al. (1993). Twelve strains originating from cases of rat-bite fever and Haverhill fever in humans and from various rodent species showed considerable serological relationship. The ELISA appeared specific since antibodies to *S. moniliformis* were absorbed by autologous and homologous antigen, but not by heterologous bacterial antigens. *Acholeplasma laidlawii* showed a partial serological relationship with *S. moniliformis*.

Recent research has used the polymerase chain reaction (PCR) to detect *S. moniliformis* (Berger et al. 2001; Boot et al. 2002). Berger et al. (2001) were able to detect *S. moniliformis* in blister fluid using their PCR technique, whereas the PCR technique developed by Boot et al. (2002) detected *S. moniliformis* infection in orally or intravenously infected rodents and in five of eight rats exposed to natural infection. Boot et al. (2002) also reported that ELISA and PCR were equally successful in detecting infection in rats.

Graves and Janda (2001) identify or confirm *S. moniliformis* isolates using four tests: (1) a growth requirement of 10–20 percent serum; (2) the presence of typical gram-negative bacilli (sometimes in chains) and filaments with bulbous swellings in a Gram stain (Figure 1a); (3) growth in broth (thioglycolate medium) with 'puff-ball' colony formation (Figure 1b); and (4) a positive direct fluorescent antibody test using an in-house-produced polyclonal antibody. *S. moniliformis* can also be identified by cellular fatty-acid profiling using gas–liquid chromatography (Rygg and Bruun 1992; Pins et al. 1996).

Susceptibility to antimicrobial agents

The bacillary form is sensitive to penicillin and to therapeutically attainable concentrations of cephalosporins, aminoglycosides, tetracycline, erythromycin, and clindamycin; it is less sensitive to chloramphenicol. The L-phase variant is resistant to penicillin but sensitive to tetracycline.

CONCLUSION

S. minus and *S. moniliformis* are the etiological agents of rat-bite fever, a disease that occurs throughout the world in areas where the rat population is heavy and the living conditions of humans are slums. Our knowledge of the fundamental microbiological characteristics of *S. minus* and the epidemiology of rat-bite fever is incomplete. More is known about *S. moniliformis*, but we do not know the true incidence of this disease nor the pathogenic mechanisms of these etiological agents. Clearly this disease and its cause deserve increased attention of microbiologists and infectious disease specialists, not only for the science involved but also to

control a disease that may be more prevalent and harmful than presently known.

Gram-negative, nonsporing, anaerobic bacilli with rounded or pointed ends, sometimes fusiform, sometimes filamentous, and often pleomorphic, that produce mixed acidic endproducts were previously classified in the genus *Bacteroides*. Recognized as important causes of human and animal infection since the latter part of the nineteenth century, they are also a major component of the normal bacterial flora of humans and animals, colonizing the mucous membranes of the mouth, urogenital, and lower gastrointestinal tract of humans. In animals they are found in the mouth and at various sites in the alimentary tract. Some species metabolize cellulose and other polysaccharides in the rumen of some herbivores; some of the most oxygen-sensitive species have been found in the cecum of chickens and other poultry.

CLASSIFICATION

The isolation and classification of these organisms has presented particular difficulties. These were partly technical, because reliable anaerobic conditions were difficult to achieve and many workers were unable to obtain pure cultures, but they also reflected the diverse properties of members of the group. There was confusion in nomenclature and disagreement between different observers over the description of the same organisms.

The classification of gram-negative anaerobic bacilli has undergone many changes since Veillon and Zuber (1898) named their isolates *Bacillus fragilis*, *Bacillus fusiformis*, etc. This was recognized by Castellani and Chalmers (1919) who proposed the genus *Bacteroides* to contain species of obligately anaerobic nonsporing bacilli. *B. fragilis* was adopted as the type species from the first edition of *Bergey's manual* (1923). Subsequently, Weiss and Rettger (1937) redefined the genus to exclude gram-positive organisms; spindle-shaped gram-negative anaerobic bacilli were placed in the genus *Fusobacterium* by Knorr (1922).

Eggerth and Gagnon (1933) produced a scheme based upon the classification of Castellani and Chalmers (1919) for the identification of strains isolated from the gastrointestinal tract. They defined 18 species on the basis of morphology and carbohydrate fermentation tests, but all of their strains were later found to belong to the *Bacteroides fragilis* group (Holdeman and Moore 1974a).

The system proposed by Prévot (1938) employed generic names that differed from those in general use and included the pigmented species *Bacteroides melaninogenicus* (proposed by Oliver and Wherry in 1921) as *Ristella melaninogenica*. He divided gram-negative anaerobic bacilli into two families, Ristellaceae with five genera (*Ristella*, *Pasteurella*, *Dialister*, *Capsularis*, *Zuberella*) and Sphaerophoraceae with two genera

(*Sphaerophorus* and *Sphaerocillus*). In the sixth edition of *Bergey's manual* (1948) the Bacteroidaceae, comprising the two genera, *Bacteroides* and *Fusobacterium*, was a tribe of the family Parvobacteriaceae. Most of the 23 species of *Bacteroides* were members of the *B. fragilis* group, except for *B. melaninogenicus*, which was described as saccharolytic, and one asaccharolytic species, *Bacteroides caviae*. In the seventh edition of *Bergey's manual* (1957), gram-negative, anaerobic bacilli were reclassified as the family Bacteroidaceae and comprised five genera. The genus *Bacteroides* contained 30 species distinguished by gas production, gelatin liquefaction, cellular morphology, and the production of acid from carbohydrates; two species were motile and two (*Bacteroides coagulans* and *Bacteroides putredinis*) were nonfermentative. There were six species of *Fusobacterium* and two of *Dialister*. The second largest genus was *Sphaerophorus* with 14 species, and aerobic but facultatively anaerobic organisms of the genus *Streptobacillus* were also included in the Bacteroidaceae. In the sixth edition of this book (1974) only three species of *Fusobacterium* and five of *Bacteroides*, and a third genus, *Dialister*, to contain the minute gram-negative bacillus *Dialister pneumosintes*, were included.

The first general agreement on taxonomy and classification was reached at the meeting of the International Commission for Systematic Bacteriology Sub-committee for gram-negative anaerobic rods at Lille in 1967, when new principles for classification were defined (Beerens 1970). These were embodied in the eighth edition of *Bergey's manual* (Holdeman and Moore 1974a). The Bacteroidaceae were divided into three genera: *Bacteroides*, *Fusobacterium*, and *Leptotrichia*. The genus *Bacteroides* contained 22 species in five groups:

1. *B. fragilis* included most of those species described by Eggerth and Gagnon (1933) and previous workers and was divided into five subspecies
2. Phenotypically similar strains that were inhibited by bile included *Bacteroides ruminicola*, *Bacteroides oralis*, *Bacteroides ochraceus*, and *Bacteroides amylophilus*
3. A group of six species that did not produce succinic acid, but were otherwise unrelated
4. Non-saccharolytic non-pigmented strains
5. *B. melaninogenicus* produced black-pigmented colonies on laked-blood agar and was divided into three subspecies.

The genus *Fusobacterium* contained 16 species that formed *n*-butyric acid as a major metabolic product and Vincent's organism (*Fusobacterium plauti-vincenti*) was assigned to the third genus, *Leptotrichia* (Gilmour et al. 1961), under the name *Leptotrichia buccalis*, because it produced lactic, but not *n*-butyric acid as a major product.

In the ninth edition of *Bergey's manual* (Holdeman et al. 1984; Jousimies-Somer et al. 2003), 42 species were assigned to the genus *Bacteroides*. These included eight species previously encompassed by '*B. fragilis*', eight species of saccharolytic nonpigmented oral bacteroides (previously '*B. oralis*'), seven saccharolytic pigmented species (previously '*B. melaninogenicus*'), three species concerned with cellulose degradation in the rumen of herbivores, and nine nonfermentative (asaccharolytic) species of which two, *Bacteroides asaccharolyticus* and *Bacteroides gingivalis*, were pigmented. In addition, three more species were proposed within the *fragilis*-like group of fecal bacteroides (*Bacteroides merdae*, *Bacteroides stercoris*, *Bacteroides caccae*; Johnson et al. 1986), another oral nonpigmented species (*Bacteroides heparinolyticus*; Okuda et al. 1985) and a third asaccharolytic pigmented species (*Bacteroides endodontalis*; van Steenbergen et al. 1984).

The genus *Bacteroides*, which contained species with a mol% content of 26–61, has undergone major taxonomic revisions (Shah 1991a, b). This was inevitable because of the considerable heterogeneity in biochemical and chemical properties that became apparent. The genus now includes species that were formerly described as the '*Bacteroides fragilis*' group. More than 15 new genera have been proposed for organisms formerly classified as *Bacteroides*, most of which are monospecific. However, two genera, *Porphyromonas* and *Prevotella* (Shah and Collins 1989, 1990), contain large numbers of species and appear to be of major clinical importance.

Comparative 16S rRNA sequence analysis has considerably reshaped the taxonomic status of the members of the family Bacteroidaceae. In this chapter, genera that cluster in the *Bacteroides* group of division 2.15 (*Flexibacter–Cytophaga–Bacteroides*) and are designated as *Bacteroides*, *Prevotella*, and *Porphyromonas*, are discussed.

Criteria for classification

Early workers relied almost exclusively upon observations of microscopic and colonial morphology. However, these properties can vary considerably among species depending on their growth conditions. Eggerth and Gagnon (1933) established the first biochemical key for the group, but their tests were performed under varied and often unsuitable conditions. Prévot (1938) used an extensive series of biochemical tests, which included the determination of metabolic endproducts. Conventional bacteriological tests remain an important part of identification schemes for gram-negative anaerobic bacilli (Holdeman and Moore 1974a; Duerden et al. 1976, 1980; Holdeman et al. 1984) and several commercial systems for rapid identification are currently available. Barnes and Goldberg (1968a, b) analyzed the data obtained from phenotypic tests by numerical methods and concluded that the most useful properties were cellular morphology, terminal pH in glucose broth, production

of formic, acetic, propionic, and butyric acids, deamination of threonine, stimulation of growth by 20 percent bile, and inhibition by certain antibiotics.

The short-chain fatty acids formed as endproducts of protein or carbohydrate metabolism were particularly important in the classification of anaerobic bacteria. They were first detected by distillation and paper chromatography (Guillaume et al. 1956), but this was superseded by gas–liquid chromatography (GLC) (Werner 1969; Moore 1970; Carlsson 1973). The family Bacteroidaceae was assigned to two principal genera, *Bacteroides* and *Fusobacterium*, on the grounds that *Fusobacterium* spp. produce *n*-butyric acid as a major product, whereas most *Bacteroides* spp. do not. The third genus, *Leptotrichia*, comprises oral fusiform bacteria that produce lactic acid as the only major product.

Several groups of workers have used comparisons of the mol% G+C content of the DNA to determine similarities and differences between members of the groups of Bacteroidaceae (Sébald 1962; Shah et al. 1976). It was a widely held view that a genus should comprise species that do not differ by more than 10–12 mol% G+C. Thus, the fact that the *Bacteroides* contained species within the range 28–61 mol% G+C indicated that several genera existed within this taxon. DNA–DNA hybridization was used to verify the intraspecies status of several taxa such as the subgroups within the *B. fragilis* group (Johnson 1973; Cato and Johnson 1976) and the subspecies of *B. melaninogenicus* (Coykendall et al. 1980; van Steenbergen et al. 1981; Shah et al. 1982).

In the mid-1970s and 1980s, attention turned increasingly towards chemical analyses of cell constituents for the provision of characters that are useful for classification. Cell wall composition, a major differentiating character among gram-positive taxa, had less impact among gram-negative bacteria. Like most gram-negative microorganisms, *Bacteroides* and *Prevotella* spp. possess a directly crosslinked peptidoglycan based upon *meso*-diaminopimelic acid, whereas some species of *Porphyromonas* appear to have a peptidoglycan structure based upon lysine (Shah et al. 1976; Hammann and Werner 1981). However, the chemical composition and structure of many species remain unknown; thus the full value of this property in the classification of these microorganisms is still to be determined. Multilocus enzyme electrophoresis using oxidoreductases provided a useful means of accentuating the diversity that existed among taxa that were considered to be homogeneous. Thus five electrophoretic patterns were found among *B. melaninogenicus* strains (Shah et al. 1976) that were subsequently assigned to different species, whereas among bacteroides considerable diversity was revealed (Shah and Williams 1982). This technique not only provided evidence of relationships and differences within the genus (Shah and Collins 1983), but also shed light on aspects of intermediary metabolism (Shah and Williams 1987a, b). The black/beige pigments produced by *B. melaninogenicus* and related taxa were regarded as one of the most important distinguishing properties. Chemical analysis revealed that the pigments were porphyrins and not melanin or ferrous sulfide as previously reported and that two major compounds existed (Shah et al. 1979; Shah 1991a). The black pigment was identified as protohemin and the fluorescent light-brown pigment was characterized as protoporphyrin (see Figure 1).

Current studies indicate that several other pigments exist and porphyrin genes are present even among nonpigmented members of the group (Shah and Gharbia, unpublished data). Gram-negative bacteria, particularly anaerobic bacteria, possess a plethora of diverse lipids, such as sphingolipids and plasmalogens (Miyagawa et al. 1978; Shah and Collins 1983). Among the lipids, long-chain cellular fatty acids (Miyagawa et al. 1979; Shah et al. 1982) have provided excellent taxonomic markers and were one of the key chemical characters used to differentiate *Porphyromonas* and *Prevotella*. In addition, analysis of polar lipids (Kunsman 1973; Kunsman and Caldwell 1974; Shah 1991b) and menaquinones (Shah and Collins 1980) have had a significant impact in reshaping the structure of the Bacteroidaceae. Menaquinones are the sole isoprenoid quinones produced by *Bacteroides* spp. and determination of the length of the C-3 polyprenyl side chains have enabled clearer circumscription of several species (Shah and Collins 1980). For example, *B. ochraceus* was shown to differ markedly from *Bacteroides* spp. in possessing menaquinones with six isoprene units. *Bacteroides* spp. and related taxa possess menaquinones with isoprene units in excess of nine. Proteins in whole cell extracts of *Bacteroides* cultures analyzed by discontinuous gradient polyacrylamide gel electrophoresis (PAGE) have been helpful in delineating specific, subspecific, and strain-specific patterns (Strom et al. 1976). Cell surface proteins released by EDTA treatment and mild sonic disintegration, and analyzed by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE), have revealed species-specific patterns among the *Bacteroides* (Poxton and Brown 1979).

The impact of rRNA sequence analysis

Initially, rRNA cataloguing and later, 5, 16, and 23S rRNA sequence analysis, were used to devise a classification system based on natural relationships (Woese 1987). Members of the Bacteroidaceae, like other taxa, were subjected to rigorous analysis and several phylogenetic trees have been constructed (see for example, Lawson et al. 1992; Paster et al. 1994; Shah et al. 1995). In general, ribosomal RNA sequence data have in the main supported previous proposals and there is now general consensus for the genera *Bacteroides*, *Prevotella*,

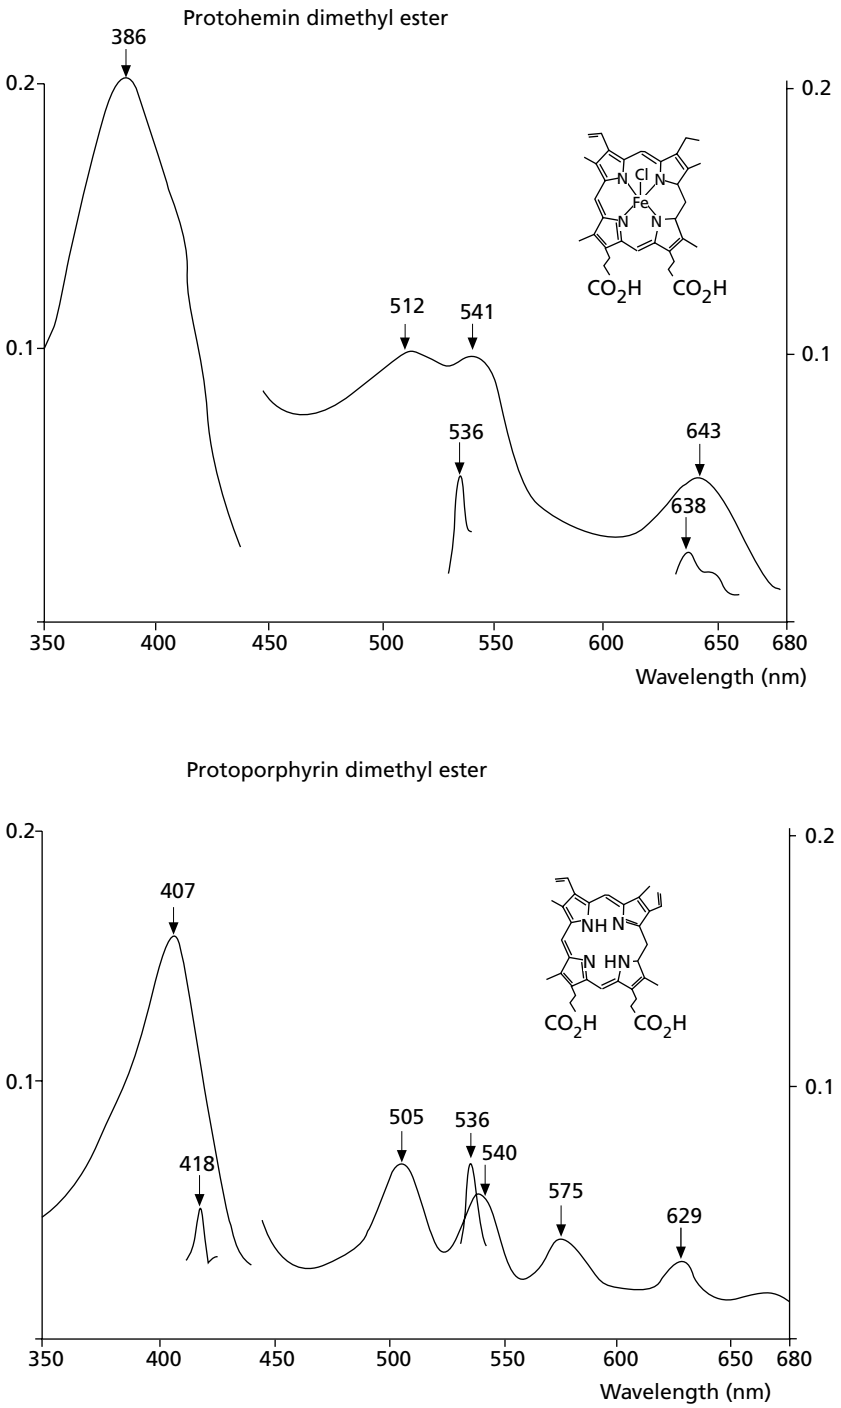

Figure 1 *The electronic spectrum and structure of the two major crystalline pigments (isolated as dimethyl esters) of* Porphyromonas *and* Prevotella *spp. The iron-containing porphyrin gives the cells their characteristic black color on blood agar plates, whereas the light brown, ultraviolet fluorescent colonies which are characteristic of some species such as* P. loescheii *are due to the production of protoporphyrin.*

and *Porphyromonas*. However, some proposals have been made using only partial 16S rDNA sequences, consequently some taxa remain in a state of flux. For example, recent studies using complete 16S rDNA sequences have confirmed that *Bacteroides splanchnicus* does not belong to the genus *Bacteroides*, while *B. merdae* and *Bacteroides distasonis*, which phenotypically resemble other members of the *Bacteroides* belong to separate lineages (see Figure 2).

Prevotella zoogleoformans, which is not inhibited by bile, and *Prevotella heparinolytica* are phenotypically different from other *Bacteroides* species and form distinct groups on the basis of 16S rDNA sequence data. Species of the genus *Prevotella* share a large number of

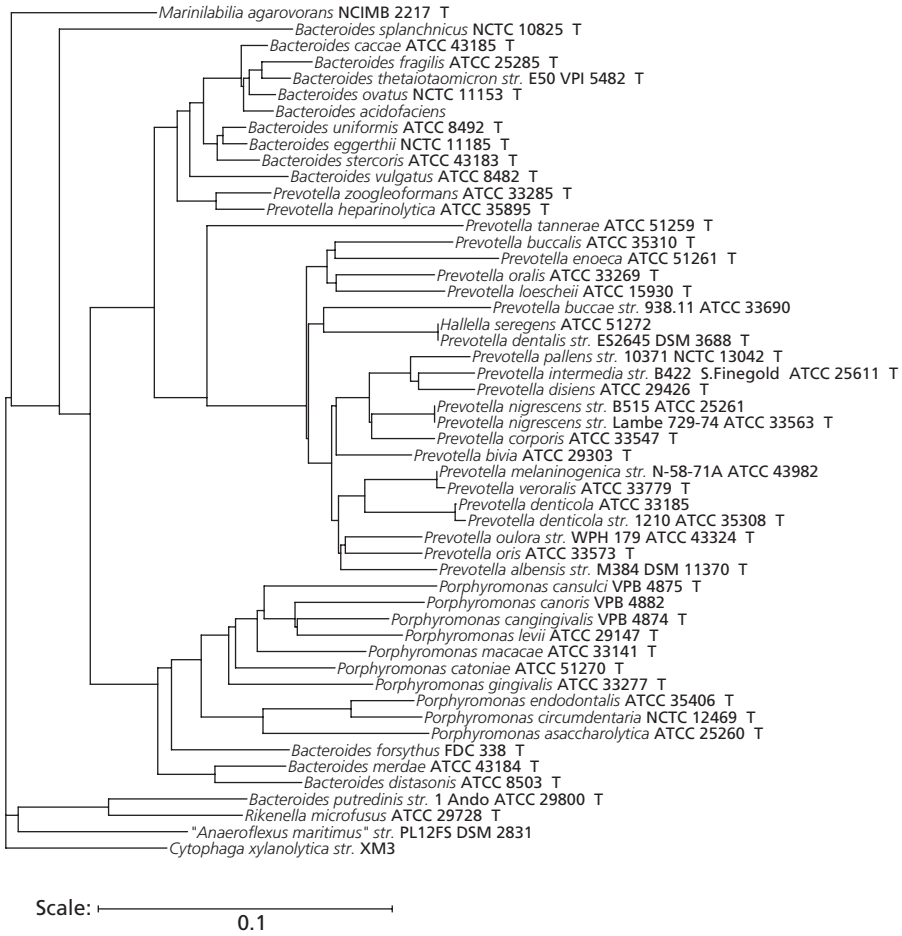

Figure 2 *Unrooted phylogenetic tree showing the position of species of the genera* Bacteroides*,* Prevotella*, and* Porphyromonas*. The tenuous relationship of several species such as* Bacteroides merdae*,* B. distasonis*, and* B. splanchnicus *are shown.* B. forsythus *was recently transferred to a new genus* Tannnerella forsythia *(see Olsen and Shah 2003).*

common traits and demonstrate high 16S rDNA sequence homologies, but there are exceptions. *Prevotella tannerae*, for example, differ from other members in cellular fatty acid composition, shows considerable sequence divergence, and is probably not a *Prevotella*, while *B. forsythus* was recently transferred to a new genus *Tannnerella forsythia* (see Olsen and Shah 2003).

BACTEROIDES

This genus contains gram-negative bacilli of closely related species that share many common properties and a common ecology. They are tolerant of bile and resistant to penicillin and are commensals in the lower gastrointestinal tract in humans. They form a major part of the normal human fecal flora and some species are important pathogens, causing infections particularly after accidental or surgical injury to the gastrointestinal tract or in association with pathological lesions of it. Most of the species described by Veillon and Zuber (1898) and by Eggerth and Gagnon (1933) were members of this group, but its classification was confused. Based on 16S rDNA sequence analysis, the current status of the genus *Bacteroides* is as shown in Table 1.

In the eighth edition of *Bergey's manual* (Holdeman and Moore 1974a) gathered all the members of this group into a single species – *B. fragilis* – with five subspecies: *fragilis*, *vulgatus*, *distasonis*, *ovatus*, and *thetaiotaomicron*. They believed that the species represented a continuum of variants with clusters of strains that were designated subspecies and smaller numbers of intermediate strains. However, Cato and Johnson (1976) found poor DNA homology between the reference strains of the five original subspecies of *B. fragilis*. They proposed that they should be reinstated to specific rank and this was accepted by the International Committee for Systematic Bacteriology (ICSB). Other clusters of strains that fell within the group were given specific status; these included *B. splanchnicus*, *B. merdae*, and *B. stercoris*. The relationship between the species remains the subject of considerable debate. They share many properties, and ecological and epidemiological studies support the concept of a closely related group. The results of a wide

Table 1 *Species of the genus* Bacteroides *with their type strain*

range of phenotypic tests on members of the fragilis group form a continuous spectrum with clusters of strains that represent the named species.

Description of the genus

The genus *Bacteroides* comprises small nonmotile gram-negative bacilli and coccobacilli; they are moderately pleomorphic, but long filaments, bizarre shapes, L-forms, and spheroplasts are rare. They grow well in 24–48 h on horse blood agar plates incubated anaerobically at 37°C to form circular, low-convex colonies, 1–3 mm in diameter with an entire edge. The colonies are usually smooth, shiny, translucent, or semi-opaque and gray. Colonies of fresh isolates are often moist and some are mucoid. Most strains do not produce hemolysis, but a few strains are slightly hemolytic and a very small proportion (<1 percent) are α-hemolytic. All species will grow on a medium that contains glucose, hemin, vitamin B_{12}, minerals, ammonium chloride, and a sulfide and is provided with a CO_2/CO_3^- buffer system. They do not use organic nitrogen compounds. They have generally been regarded as catalase-negative, but *B. fragilis* and some other saccharolytic species have been shown to produce small amounts of catalase and superoxide dismutase (Gregory et al. 1977). The G + C content of the DNA is in the range 40–48 mol% and 16S ribosomal RNA analysis revealed over 93 percent similarity among species. All species ferment a range of carbohydrates, including glucose, with the production of acid and gas. The major volatile fatty acid-products of metabolism are acetic and succinic acids; *n*-butyric acid is not produced except by *B. splanchnicus*. Most strains are stimulated by 20 percent bile and are tolerant of the bile salt sodium taurocholate, but inhibited by sodium deoxycholate. They will grow in the presence of Victoria blue 4R (1 in 80 000), but most are inhibited by gentian violet (1 in 100 000) and ethyl violet (1 in 100 000). All strains are resistant to penicillin and to high concentrations (1 000 μg disks) of neomycin and kanamycin. They decarboxylate glutamic acid but threonine is not dehydrogenated, nitrate is not reduced, and urease is not produced. Most strains hydrolyze esculin rapidly and produce acid from xylose. Members of the genus are identified by a small number of variable characteristics that include indole production, esculin hydrolysis, and the fermentation of lactose, sucrose, rhamnose, trehalose, mannitol, salicin, and arabinose (Table 2).

BACTEROIDES FRAGILIS

Isolates of this species cannot be distinguished from other members of the genus by their colonial form, or by their microscopic morphology, except that freshly isolated strains usually form a capsule. *B. fragilis* hydrolyzes esculin and produces acid from glucose, lactose, sucrose, maltose, and usually xylose, but not from rhamnose, trehalose, mannitol, salicin, or arabinose. Indole is not formed and charcoal–gelatin disks are digested slowly or not at all.

B. fragilis forms less than 10 percent of the *Bacteroides* in normal human feces, yet it is by far the most common species of *Bacteroides* to be isolated from infections related to the large intestine (Duerden 1980a). It thus appears to be particularly pathogenic for humans. This may be attributable to its possession of a polysaccharide capsule (Kasper 1976a, b) or to the action of one or more of the extracellular or membrane-associated enzymes that it forms: proteinases, including collagenase, fibrinolysin, hemolysin, neuraminidase, phosphatase, DNAase, hyaluronidase, chondroitin sulfatase, and heparinase (Gesner and Jenkin 1961; Müller and Werner 1970; Rudek and Haque 1976).

The cell wall of *B. fragilis* contains a lipopolysaccharide (LPS) with weak endotoxic activity, the polysaccharide portion of which confers type-specific O-antigenic specificity. A species-specific protein component of the outer membrane has been identified. Its presence may be used for the identification of *B. fragilis*. The pattern of proteins in the outer membrane shown by SDS-PAGE is also species-specific. External to the outer membrane is a thick polysaccharide capsule 1.5–2 times the thickness of the cell wall. It is composed of a high molecular weight polysaccharide ($>7.5 \times 10^3$ kDa). It has antiphagocytic properties and also protects the cell from complement-mediated lysis by antibodies against cell wall antigens. The capsular antigen is species-specific. This capsule is found only in *B. fragilis*. All clinical isolates of *B. fragilis* are capsulate, but the capsule is often lost on repeated subculture. It can be demonstrated in India ink preparations and identified by the Quellung reaction and in an indirect immunofluorescent assay.

+, Positive result (growth in tolerance tests); –, negative result.

BACTEROIDES VULGATUS

This species was first isolated from human feces by Eggerth and Gagnon (1933). It is the most common *Bacteroides* species in normal human feces, but is only occasionally implicated in infections. Results of tolerance tests resemble those given by other members of the genus, but approximately 50 percent of strains are tolerant of ethyl violet. Indole is not produced but charcoal–gelatin disks are digested within a few days. Unlike other members of the genus, approximately 50 percent of *B. vulgatus* strains fail to hydrolyze esculin and others do so only weakly.

BACTEROIDES DISTASONIS

This species was described by Eggerth and Gagnon (1933) in their studies of the fecal flora and named after the Romanian bacteriologist A. Distaso. Like *B. vulgatus*, it is a common member of the normal human fecal flora but seldom appears to cause clinical infections. Most strains ferment rhamnose but a significant minority do not. Indole is not produced and charcoal–gelatin disks are digested slowly or not at all.

BACTEROIDES MERDAE

Described by Johnson et al. (1986) in a study of human fecal bacteroides, this species shares the general characters of the genus. Indole is not produced, charcoal–gelatin disks may be digested slowly or not at all, and it is distinguished from other members of the genus by the ability to produce acid from trehalose and salicin, but not from rhamnose or arabinose.

BACTEROIDES CACCAE

B. caccae was described in the same study as *B. merdae* (Johnson et al. 1986), from which it is distinguished by the ability to produce acid from rhamnose, but not from salicin.

BACTEROIDES OVATUS

B. ovatus is one of the less commonly encountered species of the genus. It is not a major component of the normal fecal flora and is isolated only occasionally from clinical specimens. When present in an infection it is usually in large numbers and appears to be a significant pathogen. It produces acid from a wider range of carbohydrates than other members of the genus. The ability to produce acid from salicin and mannitol is used to identify *B. ovatus*. Indole-positive, it digests charcoal–gelatin disks within a few days.

BACTEROIDES THETAIOTAOMICRON

B. thetaiotaomicron was named by Distaso (1912) as a combination of the Greek letters theta, iota, and omicron. It is a common commensal in normal human feces and the second most common species of the genus isolated from clinical infections, where it appears to have a significant pathogenic role. Acid is not formed from mannitol by this species and a variable reaction is obtained with the charcoal–gelatin disk. Some strains digest it readily but others do so only weakly or not at all. In some studies all indole-positive members of the genus that were not *B. ovatus* were assigned to *B. thetaiotaomicron*. However, other indole-positive subgroups or species are known.

BACTEROIDES EGGERTHII

B. eggerthii was named after the American bacteriologist A.H. Eggerth and described by Holdeman and Moore (1974b) following their studies on the human fecal flora. Acid formation from rhamnose but not sucrose distinguishes *B. eggerthii* from other indole-positive species of the genus. Isolates are able to digest charcoal–gelatin disks.

BACTEROIDES UNIFORMIS

This species was described by Eggerth and Gagnon in 1933. The organisms are normally found in human feces, but rarely implicated in clinical infections. In many studies, strains of *B. uniformis* have been included with other indole-positive strains as *B. thetaiotaomicron*. Like *B. variabilis*, some strains that grow well in 20 percent broth are inhibited by sodium taurocholate. Charcoal–gelatin disks are usually digested within a few days.

BACTEROIDES STERCORIS

B. stercoris was described by Johnson et al. (1986) in a study of human fecal bacteroides. Acid is produced from sucrose and rhamnose but not from trehalose, arabinose, or salicin and this distinguishes it from other indole-positive species of the *Bacteroides*.

BACTEROIDES SPLANCHNICUS

B. splanchnicus has been isolated from normal human feces and from several infections related to the lower gastrointestinal tract (Werner et al. 1975); in particular, several strains were isolated in significant numbers from infectious complications of appendicitis. It shares many characters with other members of the *Bacteroides*, but differs from them in one important respect: it is the only fermentative species of *Bacteroides* to form significant amounts of *n*-butyric acid. This it does in addition to forming a variety of other acids including *iso*-valeric, *iso*-butyric, and propionic acids, as well as acetic and succinic acids that are produced by all members of the *Bacteroides*. A minority of strains that grow well in 20 percent bile broth are inhibited by sodium taurocholate. Some strains digest charcoal–gelatin disks, but others do not. This species shares many chemotaxonomic properties with members of the genus *Porphyromonas* and the result of 16S rRNA sequence analysis suggests that it is a separate lineage (Figure 2).

PREVOTELLA

Oliver and Wherry (1921) described gram-negative anaerobic bacilli that produced black pigmented colonies when grown on blood agar. They called their strains *Bacterium melaninogenicum*; subsequently all pigmented strains were assigned to the species *Bacteroides melaninogenicus*. This characteristic appearance was regarded as highly specific and was the sole criterion for differentiation from other *Bacteroides* spp. Confusion surrounded studies on *B. melaninogenicus* because of the diversity of characters among pigmented strains and because of the specific requirements of some strains for growth factors such as vitamin K (Lev 1959), hemin, and sodium succinate. Some *B. melaninogenicus* strains isolated from the normal flora, particularly the gingival crevice, are nutritionally demanding and require a variety of growth factors provided by cocultivation with other bacteria, but as yet are unidentified.

The pigmented strains appeared to share several characters in addition to pigmentation, but there were major differences in metabolic and biochemical activity between groups, and *B. melaninogenicus* was divided into three subspecies: *melaninogenicus*, *intermedius*, and *asaccharolyticus* (Sawyer et al. 1962; Moore and Holdeman 1973). Studies of cell wall composition and DNA base ratios supported this division (Shah et al. 1976). Werner et al. (1971) found that pigmented strains from human feces and from infections related to the lower gastrointestinal tract formed a homogeneous group of asaccharolytic strains and recognized only these as *B. melaninogenicus*. The differences between the subspecies cast doubt upon the validity of assigning all pigmented strains to a single species. The asaccharolytic strains were distinguished from the saccharolytic strains by their production of *n*-butyric acid and also by differences in G + C content of the DNA and in cell wall composition. The ICSB taxonomic subcommittee on gram-negative anaerobic rods (Finegold and Barnes 1977) therefore proposed that the asaccharolytic strains should be classified as a separate species, *B. asaccharolyticus*. Further differences were found subsequently between *B. asaccharolyticus* strains associated with the intestinal flora and with superficial necrotizing infections, and pigmented nonfermentative strains associated with periodontal disease and dental root-canal infections. The latter two groups of isolates were assigned species status as *B. gingivalis* (Coykendall et al. 1980) and *B. endodontalis* (van Steenbergen et al. 1981), respectively, and both were later placed in the genus *Porphyromonas* (Shah and Collins 1988).

The fermentative pigmented species that remained ('*B. melaninogenicus*') was also heterogeneous and was divided into several distinct species. *B. melaninogenicus* subspecies *melaninogenicus* was shown to comprise three species – *B. melaninogenicus* (sensu stricto), *Bacteroides loescheii*, and *Bacteroides denticola* (Holdeman and Johnson 1982) – whereas *B. melaninogenicus* subspecies *intermedius* was divided into two species, *Bacteroides intermedius* and *Bacteroides corporis* (Johnson and Holdeman 1983). Before the elevation to species status, a weakly fermentative subspecies *levii* was proposed. The latter has now been elevated to species rank as *Porphyromonas levii* (Shah et al. 1995) and a second weakly fermentative species, *Porphyromonas macacae* (synonymous with *Porphyromonas salivosa*) has been proposed.

It is now clear that the production of pigmented colonies on media that contain blood has less taxonomic significance than was previously thought and both *Prevotella* and *Porphyromonas* include nonpigmented species. Formerly the *B. melaninogenicus-oralis* group included the fermentative pigmented species and several nonpigmented species that shared many common characters. The species *B. oralis* was originally proposed for nonpigmented bile- and penicillin-sensitive strains of *Bacteroides* isolated from the human mouth (Loesche et al. 1964), but the type strain of *B. oralis* proved to be pigmented and was first reclassified as *B. melaninogenicus* subspecies *melaninogenicus* (Holbrook and Duerden 1974) and subsequently as *B. loescheii* (Holdeman and Johnson 1982). However, other nonpigmented strains were described that corresponded to the original description of *B. oralis* or appeared to be related to it. These were represented by *B. oralis*, *Bacteroides veroralis* (Watabe et al. 1983), *Bacteroides oris*, *Bacteroides buccae* (Holdeman et al. 1982), *Bacteroides zoogleoformans* (Cato et al. 1982), and *Bacteroides buccalis* (Shah and Collins 1981). Two other nonpigmented members of the melaninogenicus-oralis group, *Bacteroides disiens* and *Bacteroides bivius*, were isolated from human clinical infections by Holdeman and Johnson (1977) and have since been found in the normal vaginal flora and infections of the genitourinary tract, and occasionally in the mouth.

Description of the genus

The organisms are gram-negative, obligately anaerobic, nonspore-forming, nonmotile pleomorphic rods. Surface colonies on blood agar plates vary from minute to 2.0 mm in diameter and are generally circular, entire, convex, shiny, and smooth. Colonies on blood agar are translucent, opaque, gray, light brown, or black. Hemolysis is variable. Glucose broth cultures are usually turbid with smooth or stringy sediments, and the terminal pH is between 4.5 and 5.2. The optimum temperature for growth is 37°C, but some strains grow at 25 and 45°C. Growth of most species is inhibited by 6.5 percent NaCl. Hemin and menadione are required for growth of most species. Growth is inhibited by 20 percent (w/v) bile. They are inhibited by sodium taurocholate and

sodium deoxycholate and will not grow in 20 percent bile broth. They are inhibited by most dyes but many strains are tolerant of Victoria blue 4R (1 in 80 000). In antibiotic resistance tests, most strains are sensitive to neomycin (1 000 μg), rifampicin (15 μg), and resistant to kanamycin (1 000 μg) disks. Many strains are sensitive to benzylpenicillin, but some strains of all species of the genus are resistant as a result of plasmid-coded β-lactamase production. Threonine is not dehydrogenated. The major fermentation products are acetic and succinic acid. Occasionally lower levels of *iso*-butyric, *iso*-valeric or lactic acid are produced. Proteolytic activity is variable. Nearly all species are indole-negative. Nitrate is not reduced to nitrite. The cell wall peptidoglycan contains *meso*-diaminopimelic acid. The principal respiratory quinones are unsaturated menaquinones, often with 10–13 isoprene units. Both nonhydroxylated and 3-hydroxylated fatty acids are composed of predominantly straight-chain saturated, *anteiso*- and *iso*-methyl, branched-chain types. Sphingolipids are produced. The DNA base compositions are within the range of 40–52 mol% G+C. Other currently described species that conform to the generic description of *Prevotella* are given in Table 3. The genus was emended by Willems and Collins (1995c) to include species that are phylogenetically coherent but possess DNA base compositions within the range 40–60 mol% G+C. The type species is *Prevotella melaninogenica* (Table 4). Characteristics that differentiate species of the genus *Prevotella* are given in Table 3, while those that differentiate the pigmented species (*Prevotella* and *Porphyromonas*) are given in Table 5.

PREVOTELLA MELANINOGENICA

P. melaninogenica is a common commensal in the human gingival crevice and in the vagina and is found in infections related to these sites. Most strains are short gram-negative bacilli or coccobacilli and many are moderately pleomorphic. Colonies are 1–2 mm in diameter, round, convex, and opaque. After incubation for 48 h, they are typically light gray, becoming brown after further incubation. Pigmentation develops more rapidly on lyzed blood agar and varies between strains from light brown to almost black. It begins in the center of the colony and the colonies of many strains have a light brown or pale annulus around a dark-brown center. Charcoal–gelatin disks are digested within a few days. The G + C content of the DNA is 40–42 mol% (Shah et al. 1976). Strains contain a peptidoglycan based upon *meso*-diaminopimelic acid.

PREVOTELLA LOESCHEII

This pigmented species is named after W.J. Loesche. The type strain is ATCC 15930, originally designated *B. oralis*. Pigment production is fairly slow, but is enhanced by growth on lyzed blood agar. Ability to hydrolyze esculin distinguishes it from *P. melaninogenica*. The DNA G + C content is 46–48 mol%.

PREVOTELLA DENTICOLA

Described by Shah and Collins (1981), this pigmented species is found in the gingival crevice and in human clinical specimens from sites in and around the mouth. It is distinguished from *P. melaninogenica* and *P. loescheii* by tests for hydrolysis of esculin and fermentation of cellobiose. The G + C content of its DNA is 49–51 mol%.

PREVOTELLA INTERMEDIA AND *PREVOTELLA NIGRESCENS*

Isolates of these species initially belonged to *P. intermedia*. They are associated with the gingival crevice and are often isolated from cases of gingivitis and other purulent lesions related to the mouth. Most strains are

short gram-negative bacilli and coccobacilli and many are pleomorphic. The colonies are 1–2 mm in diameter, round, convex, and opaque. After incubation for 48 h, isolated colonies are typically gray, but become uniformly black after further incubation. Some strains are shiny and glistening, but others are dull with a rough, dry surface and these may adhere to the underlying medium. Pigmentation develops more rapidly on lyzed blood agar. Most strains produce clear zones of complete hemolysis in blood agar and are inhibited by Victoria blue 4R. Strains produce indole, readily digest charcoal–gelatin disks and do not ferment lactose. The G + C content of the DNA is 40–42 mol%. Lambe and Jerris (1976) described two distinct serogroups. Johnson and Holdeman (1983) have described two DNA homology groups, which were recently confirmed (Shah and Gharbia 1992) using multilocus enzyme electrophoresis, DNA–DNA homology and subsequently 16S rRNA sequence analysis. This resulted in the proposal of the species *P. nigrescens* for the second homology group.

PREVOTELLA CORPORIS

P. corporis was described by Johnson and Holdeman (1983) to represent strains isolated from clinical human specimens previously considered to be *P. intermedia*, but which do not produce indole or ferment sucrose. The DNA G + C content is 43–46 mol%.

PREVOTELLA ORALIS

Strains that correspond to the original description (Loesche et al. 1964) are an important component of the normal flora of the gingival crevice, and similar strains have been isolated from the normal vagina. Nonpigmented oral strains have also been implicated in infections derived from these sites. All these infections are associated with tissue necrosis and the production of foul-smelling pus. Colonies of *P. oralis* are 1–2 mm in diameter, semi-opaque, and light-buff or gray. After prolonged incubation some become pale brown and some develop a spreading edge with an irregular outline. Most strains are predominantly coccobacillary but a few produce longer, more regular bacilli. Most strains hydrolyze esculin and digest charcoal–gelatin disks within a few days.

PREVOTELLA PALLENS

P. pallens isolates were separated from *P. nigrescens* based on their weak pigmentation of colonies on blood agar plates. A distinct halo of metallic sheen is seen around the colonies and exhibit red fluorescence under UV light. All strains are resistant to vancomycin but susceptible to colistin.

PREVOTELLA VERORALIS

This species differs from *P. oralis* in failing to ferment salicin and has negligible DNA homology with that species (Watabe et al. 1983). It more closely fits the original description of *P. oralis* (Loesche et al. 1964) than the strains now designated *P. oralis*. The DNA G + C content is 42 mol%.

PREVOTELLA BUCCALIS

P. buccalis is indistinguishable from *P. veroralis* in most routine conventional tests and has a similar DNA base composition. However, unlike *P. veroralis*, it produces *iso*-valeric acid as a major metabolic product and it does not hydrolyze starch (Watabe et al. 1983). These differences are supported by lack of DNA homology between *P. buccalis* strains and other *Prevotella* spp.

PREVOTELLA ZOOGLEOFORMANS

This species was described by Weinberg et al. (1937), and Prévot (1938) proposed a new genus *Capsularis* for these strains. Moore et al. (1994) emended the description of the species. No early strains remain extant, but Cato et al. (1982) isolated strains that fulfilled the description from the gingival crevice of patients with periodontal disease. The specific epithet '*zoogleoformans*' represents the character of this organism's growth in broth culture. It forms a viscous, glutinous mass, especially in the presence of fermentable carbohydrate.

a) See Table 3, footnote a. + [w], most strains positive; some strains weakly positive.
b) Reaction by the API ZYM system or with Rosco Diagnostic Tablets (see Table 4, footnote b). Reactivity in these systems in not always identical (see footnote f).
c) See Table 3, footnote c.
d) Nonpigmented.
e) *P. gingivalis* does not show fluorescence; *P. kevii-like* may show weak or no fluorescence.
f) Negative by the API ZYM system; positive by the Rosco *o*-nitrophenyl-β-d-galactopyranoside test.
g) May be isolated from bite infections; NA, information not available.
h) *P. intermedia* shares the same characteristics. Differentiation based on enzyme electrophoresis, oligonucleotide probe analysis, or arbitrarily primed PCR.

Most strains except the type strain produce indole, ferment cellobiose, and hydrolyze esculin. The major cellular fatty acids are predominantly *iso*-$C_{15:0}$ and *anteiso*-$C_{15:0}$ acids. The G + C content of the type strain ATCC 33285 is 47 mol%. Recently rRNA sequence analysis has indicated a closer affinity with the genus *Bacteroides*.

PREVOTELLA ORIS AND *PREVOTELLA BUCCAE*

These two species accommodate strains of human origin that were previously identified as *B. ruminicola* subspecies *brevis* biovar (biotype) 3. Similar strains have been isolated from chicken ceca. The human isolates are mostly from gingival margins and periodontal pockets and infections at related sites. They differ from *P. oralis* by their ability to ferment pentoses, which is the reason for their earlier confusion with *P. ruminicola*. The DNA G + C content for *P. oris* is 42–46 mol%, whereas for *P. buccae* it is 50–52 mol% (Holdeman et al. 1982).

PREVOTELLA HEPARINOLYTICA

Isolated from patients with periodontitis, this species produces acid from a range of sugars, including pentoses, is indole-positive, hydrolyzes esculin, and produces heparinase (Okuda et al. 1985). rRNA sequence analysis indicates a closer affinity with the genus *Bacteroides*.

PREVOTELLA OULORA

P. oulora is also found in the mouth. It ferments only a limited range of sugars, is indole-negative, and does not hydrolyze esculin. It produces a lipase (Shah et al. 1985).

PREVOTELLA BIVIA

Isolated from human infections by Holdeman and Johnson (1977), this is the most common species of *Prevotella* in the normal human vaginal flora (Duerden 1980b). Most clinical isolates are from infections related to the female genital tract. It cannot be recognized by cell morphology or colonial appearance and does not form pigment, but colonies are often pale brown after prolonged incubation on lyzed blood agar. Few strains hydrolyze esculin, but charcoal–gelatin disks are digested within a few days. The DNA G + C content is 40 mol%.

PREVOTELLA DISIENS

Described by Holdeman and Johnson (1977) at the same time as *P. bivia* and isolated from similar infections and from the normal vaginal flora, strains of *P. disiens* differ from *P. bivia* by their inability to ferment lactose. The DNA G + C content is 40–42 mol%.

PREVOTELLA DENTALIS

Isolates of this species were previously reported as *Hallella seregens* or *Mitsuokella dentalis*. rRNA sequence analysis confirmed that they are similar and are genealogically related to *Prevotella* (Willems and Collins 1995c). Strains are isolated from dental root canals and are distinguished from other *Prevotella* spp. by the typical water drop appearance of its colonies on solid medium. The DNA G + C content is 56–60 mol%.

PREVOTELLA ENOECA

This saccharolytic species was isolated from the gingival crevice of humans. Colonies are small, 1–2 mm in diameter, nonhemolytic, nonpigmented, and strains characteristically ferment glycogen and lactose, but not sucrose, and are unable to ferment gelatin. The endproducts of metabolism are acetic and succinic acids and, in common with most *Prevotella* spp., *P. enoeca* contains *anteiso*-$C_{15:0}$ as its major cellular fatty acid. The G + C content of the type strain ATCC 51261 is 47 mol%.

PREVOTELLA TANNERAE

This species colonizes the human gingival crevice and contains strains that produce small, circular colonies, 1 mm in diameter, that may be black, tan to brown, reddish, or colorless on rabbit blood agar medium. Most strains are unable to hydrolyze esculin, but produce acid from glycogen and lactose. The fermentation acids are mainly succinic and acetic with lower levels of formic, *iso*-valeric and *iso*-butyric acids. Its major cellular fatty acids are *iso*-$C_{15:0}$ and *anteiso*-$C_{15:0}$ acids. The G + C content of the type strain ATCC 51259 is 45 mol%.

PREVOTELLA RUMINICOLA

This species is isolated from the rumen and from the hindgut of many mammalian species. Most strains produce clear zones which are visible after staining with congo red. Most strains ferment arbutin and salicin, and are stimulated by heme in the absence of rumen fluid. The DNA G + C content is 45–52 mol%.

PREVOTELLA ALBENSIS

P. albensis is isolated from the rumen and from the hindgut of many mammalian species. Strains do not ferment melibiose, sucrose, or mannose, but ferment xylose. The DNA G + C content is 39–43 mol%.

PREVOTELLA BREVIS

P. brevis is isolated from the rumen and from the hindgut of many mammalian species. Most strains produce abundant extracellular DNAase activity and do not ferment xylose. Many strains can grow with gum arabic as an energy source. The DNA G + C content is 45–52 mol%.

PREVOTELLA BRYANTII

P. bryantii is isolated from the rumen and from the hindgut of many mammalian species. Most strains

produce abundant extracellular DNAase and ferment xylose. The DNA G + C content is 39–43 mol%.

NEW *PREVOTELLA* SPECIES

Following the completion of this chapter, two new *Prevotella* species: *Prevotella shahii* sp. nov. and *Prevotella salivae* sp. nov. have been proposed (see Sakamoto et al. 2004).

PORPHYROMONAS

Description of the genus

Porphyromonas spp. are gram-negative, obligately anaerobic nonspore-forming, nonmotile rods, or coccobacilli (Table 5). Most cells in broth are small (0.5–0.8 by 1.0–3.5 μm), but occasionally longer cells (4–6 μm) may be formed. Surface colonies on blood agar plates are smooth (rarely rough), shiny, convex, circular, entire, and vary from minute to 3.0 mm in diameter and darken progressively from the edge toward the center after 6–10 days. Eventually the entire colony becomes black due to an overproduction of protoheme. The optimum temperature for growth is 37°C. Growth is not significantly affected by carbohydrates. Nitrogenous substrates such as proteose peptone, trypticase, and yeast extract markedly enhance growth. The major fermentation products from media containing these substrates are *n*-butyric, propionic, and acetic acids with lower levels of *iso*-butyric, *iso*-valeric, succinic, and phenylacetic acids. Some species are strongly proteolytic, whereas others show weak peptidase activities. In general there is a paucity of reliable characters for differentiation of these species (see Table 5), thus new techniques such as matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF-MS) may be useful in helping to delineate these species (see, for example, Figure 3) (Shah et al. 2000, 2002).

Malate and glutamate dehydrogenases are present in cell extracts. With the exception of a few species isolated from animals, glucose-6-phosphate and 6-phosphogluconate dehydrogenases are absent. Amino acids, particularly aspartic and glutamic acids, are fermented. Indole is produced by most species and nitrate is not reduced to nitrite.

Growth of all the pigmented species is inhibited by vancomycin. The cell wall peptidoglycan contains lysine or *meso*-diaminopimelic acid. The principal respiratory quinones are unsaturated menaquinones. Both nonhydroxylated and 3-hydroxylated fatty acids are present. The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl branched-chain types (*iso*-$C_{15:0}$) and lower levels of straight-chain saturated types. The 3-hydroxylated fatty acids are the straight-chain saturated types. Sphingolipids are produced. The DNA base compositions are within the range 40–55 mol% G + C. Salient phenotypic features of the species of the genus are given in Table 5. The genus was emended recently by Willems and Collins (1995b) to include species that are phylogenetically coherent, but lack some of the key features of the original description of this genus, such as pigment production and their inability to ferment carbohydrates. The type species of the genus *Porphyromonas* is *Porphyromonas asaccharolytica*.

PORPHYROMONAS ASACCHAROLYTICA

These organisms are mainly coccobacilli with only a few slightly longer bacilli. Very small colonies may be visible

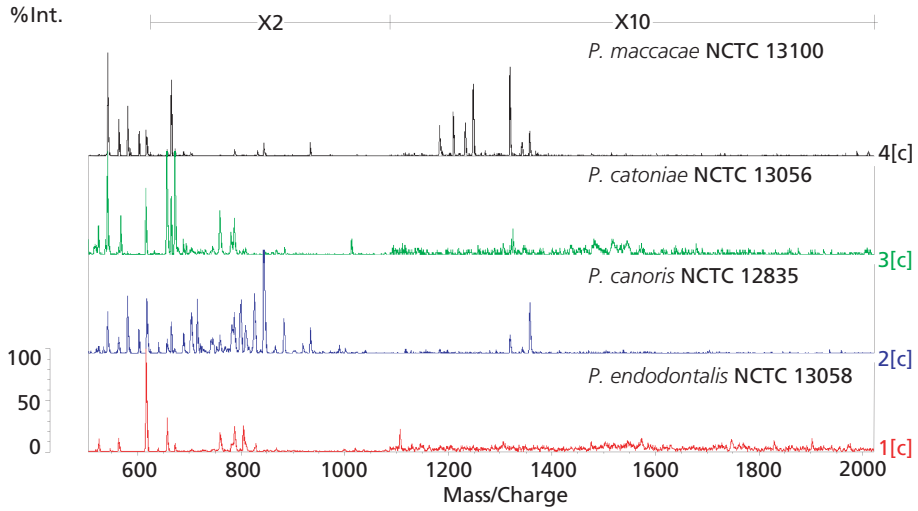

Figure 3 *Differentiation of four species of* Porphyromonas *using MALDI-TOF-MS of intact cell surfaces. The mass ions (m/z value) of the surface components of the cell is given along the horizontal axis, while the mass intensities (0–100 percent) of each spectrum is shown by the peak height. The results show that the mass spectral fingerprint of each species is dintinctive, therefore species may be characterized by reference to a database of existing spectra.*

on blood agar after 24 h, but some strains do not appear for 48 h. They are smooth, shiny, and grey or brown. Pigmentation begins to develop after 3–4 days on whole blood agar, but may be visible in the inoculum after 36–48 h on lyzed blood agar. After 4–5 days, colonies are 0.5–1 mm in diameter, black or very dark brown. The colonies are smooth and shiny; they are often very moist and can be smeared over the agar surface, although the organisms do not produce large amounts of extracellular mucus. Most strains have a characteristically strong, putrid smell. The major endproducts of metabolism in a cooked meat–carbohydrate medium are *n*-butyric and acetic acids together with lower levels of propionic, *iso*-butyric and *iso*-valeric acids. *P. asaccharolytica* is inhibited by bile and bile salts and by dyes, resistant to kanamycin and sensitive to penicillin and rifampicin. Most strains are sensitive to neomycin (1 000 μg per disk), but some are resistant. *P. asaccharolytica* does not agglutinate sheep or horse erythrocytes (Slots and Genco 1979). The G+C content of the DNA is 52–54 mol%. *P. asaccharolytica* is found in normal human feces, but less consistently and in smaller numbers than *Bacteroides* spp. It has also been reported in the normal vagina. It is an important pathogen in mixed infections but is rarely isolated alone. It is found in infections related to the lower gastrointestinal tract and in destructive ulcers and gangrene in diabetics and others with peripheral vascular disease. It should be noted that early work on the experimental pathogenicity of '*B. melaninogenicus*' (Werner et al. 1971) was probably done with *P. asaccharolytica*.

PORPHYROMONAS CANGINGIVALIS

This species is isolated from the subgingival flora of dogs. Cells are coccoids, 0.3–0.6 μm, and occur singly or in clumps. Occasionally filaments up to 16 μm long are observed. On sheep blood agar plates, surface colonies after 2 days are 1 mm in diameter, circular, dome-shaped, nonhemolytic, and smooth. Colonies are poorly pigmented and creamy after 3–5 days and by 10 days are light brown. On egg yolk agar, colonies are yellow or orange. This species produces acetic, propionic, *iso*-butyric, *n*-butyric, *iso*-valeric, succinic, and phenylacetic acids as metabolic endproducts. Strains produce catalase and acid and alkaline phosphatases, but do not produce any proteinases or lipases. The G+C content of the DNA is 49–51 mol%.

PORPHYROMONAS CANORIS

Isolated from the gingival sulcus of dogs, the cells are rod-shaped and are 0.3–0.6 by 0.8–1.5 μm, but filaments up to 16 μm are sometimes present. After growth for 48 h on sheep blood agar plates, surface colonies are 1.5 mm in diameter, circular, rough, and have an orange pigmentation. Between 3 and 6 days colonies exhibit a brick red fluorescence when irradiated with shortwave UV radiation (265 nm), but this changes to a light orange after 13 days. Pigmentation occurs faster with laked blood. The major endproducts of metabolism in cooked meat–carbohydrate medium are acetic, propionic, *iso*-valeric, and succinic acids together with low levels of *n*-butyric and *iso*-butyric acids. Lactate is converted to propionate, but neither pyruvate nor threonine is utilized. Strains are catalase-, acid- and alkaline phosphatase-positive, liquefy gelatin, and possess chymotrypsin activity. Both acid and alkaline phosphatases are produced. A wide spectrum of oxidoreductases are produced, including malate, glutamate, glucose-6-phosphate, and 6-phosphogluconate dehydrogenases. The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl branched types, with *iso*-$C_{15:0}$ acid predominating. The G+C content of the DNA is 49–51 mol%.

PORPHYROMONAS CANSULCI

This species is isolated from the subgingival flora of dogs. Cells are coccoid, 0.3–0.6 μm, and occur singly or in groups. On sheep blood agar plates, surface colonies after 3 days are 1–2 mm in diameter, circular, dome-shaped, and smooth. Colonies are black or brown after 5 days. On egg yolk agar colonies are yellow or orange. This species produces a wide spectrum of fermentation products that includes acetic, propionic, *iso*-butyric, *n*-butyric, *iso*-valeric, succinic, and phenylacetic acids. Neither lactate nor pyruvate is utilized and threonine is not converted to propionate. Strains produce catalase and acid and alkaline phosphatases, but do not produce any proteinases or lipases. The G+C content of the DNA is 49–51 mol%.

PORPHYROMONAS CATONIAE

Isolated from the gingival crevice of humans, strains were of uncertain taxonomic designation initially and were temporarily placed in a group referred to as '*Bacteroides* D26'. These were subsequently assigned to a new genus, *Oribaculum catoniae*, by Moore and Moore (1994), but later transferred to the genus *Porphyromonas* by Willems and Collins (1995b) based on comparative analysis of approximately 96 percent of the total primary sequence of the 16S rRNA. At present, this is the only nonpigmented and saccharolytic member of the genus. Colonies on blood agar plates are 0.5–2 mm in diameter, circular, entire flat to low convex, and transparent. Cells grown in a glucose-containing medium (e.g. peptone–yeast extract–glucose (PYG)) produce a terminal pH of 5.0–5.5 and their metabolic endproducts are mainly acetic and succinic acids with low levels of formic, lactic, and *iso*-valeric acids. The major cellular fatty acids are *iso*-$C_{15:0}$ and *anteiso*-$C_{15:0}$ but substantial levels of *iso*-$C_{13:0}$ are also produced. The DNA base compositions are in the range 49–51 mol% G+C.

PORPHYROMONAS CIRCUMDENTARIA

This species is isolated from soft tissue infections, the gingival margins, and gingival plaques of cats. On sheep blood agar plates, colonies after 72 h are 1–2 mm in diameter, circular, entire, dome-shaped, and are greenish brown, but become creamy brown by 7 days. During this period, colonies exhibit a brick red fluorescence when irradiated with shortwave UV radiation (254 nm). By 14 days, colonies are brown to black. Cells are rod-shaped and are 0.3–0.6 by 0.8–1.5 μm, but filaments up to 10 μm are sometimes present. The major endproducts of metabolism in cooked meat–carbohydrate medium are acetic, *n*-butyric, and *iso*-valeric acids with lower levels of propionic, *iso*-butyric, succinic, and phenylacetic acids. Strains are catalase-positive, produce ammonia, and liquefy gelatin. Both acid and alkaline phosphatases are produced. The G + C content of the DNA is 40–42 mol%.

PORPHYROMONAS CREVIORICANS

P. crevioricans is isolated from the gingival crevicular fluid of beagle dogs. Colonies on rabbit blood agar plates after 72 h are tiny, 0.8–1.5 mm in diameter, circular, entire, dome-shaped, opaque, and brown or black. The major endproducts of metabolism in GAM medium (Nissul, Tokyo, Japan) are acetic, propionic, and *iso*-valeric acids with lower levels of *n*-butyric, *iso*-butyric, succinic, and phenylacetic acids. Malate and glutamate dehydrogenases are present in cell extracts, but glucose-6-phosphate and 6-phosphogluconate dehydrogenases are absent. Cells hemagglutinate sheep erythrocytes. Strains so far tested (Hirasawa and Takada 1994) are susceptible to penicillin (0.5 U per disk), amoxycillin (2 μg per disk), sulbenicillin (5 μg per disk), and erythromycin (0.5 μg per disk). The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl branched types, with *iso*-$C_{15:0}$ acid predominating. The G + C content of the DNA is 44–45 mol%.

PORPHYROMONAS ENDODONTALIS

This pigmented species is more difficult to culture on primary isolation, but becomes easier to maintain with repeated subculture. Initially, colonies are very sticky and adhere strongly to the medium. It is isolated from infected dental root canals with severe periapical destruction (van Steenbergen et al. 1984). Colonies on blood agar plates are shiny, smooth, convex, and circular. Major fermentation products are *n*-butyric and acetic acids. Lower levels of propionic, *iso*-butyric, and *iso*-valeric acids are produced, but phenylacetic acid is not produced. The G + C content of the DNA is 49–51 mol%.

PORPHYROMONAS GINGIVALIS

Cells are nonmotile rods or coccobacilli and are 0.5–2 μm long. Colonies on blood agar are smooth, shiny, convex, and 1–2 mm in diameter and darken from the edge of the colony toward the center between 4 and 8 days. Nonpigmented colonies rarely occur. Growth is markedly affected by the presence of protein hydrolysates such as trypticase, proteose peptone, and yeast extract. Growth is enhanced by 0.5–0.8 percent NaCl. Major fermentation products are *n*-butyric and acetic acids. Lower levels of propionic, *iso*-butyric, *iso*-valeric, and phenylacetic acids are also produced. Cysteine proteinases and collagenases are present. Cells agglutinate sheep erythrocytes. Cell wall peptidoglycan contains lysine as the diamino acid. Both nonhydroxylated and 3-hydroxylated fatty acids are present. The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl-branched types, with *iso*-$C_{15:0}$ acid predominating. The major respiratory quinones are menaquinone with nine isoprene units. The G + C content of the DNA is 46–48 mol%.

PORPHYROMONAS GINGIVICANS

This species is isolated from the gingival crevicular fluid of beagle dogs. Colonies on rabbit blood agar after 72 h are tiny, 0.8–1.5 mm in diameter, circular, entire, dome-shaped, opaque, and brown or black. The major endproducts of metabolism in GAM medium (Nissul, Tokyo, Japan) are acetic, *n*-butyric, and *iso*-valeric acids with lower levels of propionic, *iso*-butyric, and succinic acids. Malate and glutamate dehydrogenases are present in cell extracts, but glucose-6-phosphate and 6-phosphogluconate dehydrogenases are absent. Strains are catalase-positive. Cells neither agglutinate sheep erythrocytes nor exhibit trypsin nor *N*-acetyl-β-glucosaminidase activity. Strains so far tested (Hirasawa and Takada 1994) are susceptible to penicillin (0.5 U per disk), amoxycillin (2 μg per disk), sulbenicillin (5 μg per disk), and erythromycin (0.5 μg per disk). The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl-branched types, with *iso*-$C_{15:0}$ acid predominating. The G + C content of the DNA is 41–42 mol%.

PREVOTELLA GULAE

Described by Fournier et al. (2001), this species was isolated from the subgingival plaque of several animals. Strains are catalase-positive and produce indole. A brown pigment is produced on aging of the cultures, but colonies do not fluoresce under UV light. The DNA G + C content is 51 mol%.

PORPHYROMONAS LEVII

Named after M. Lev, who isolated it from cattle (Lev 1959), this species produces dark brown colonies slowly on blood agar and more promptly on lyzed blood agar. Unlike most pigmented members of the genus, it is weakly fermentative and weakly ferments glucose and lactose, but not other carbohydrates. Charcoal–gelatin disks are digested within a few days. *P. levii* produces

n-butyric acid as its major product of metabolism with moderate levels of acetic, propionic, *iso*-butyric, and *iso*-valeric acids. The nonhydroxylated fatty acids are composed of major levels of *iso*-$C_{15:0}$ and *anteiso*-$C_{15:0}$ acids. The G + C content of the DNA is 45–48 mol%.

PORPHYROMONAS MACACAE

This species is weakly fermentative and has been isolated from periodontal lesions in monkeys (Slots and Genco 1980). Strains are catalase-positive, produce ammonia, and possess both trypsin and chymotrypsin activities. Strains are indole-positive and are further distinguished from *P. levii* by production of propionic acid and not butyric acid as the major metabolic product. This species possesses a wide spectrum of oxidoreductases that include malate, glutamate, glucose-6-phosphate, and 6-phosphogluconate dehydrogenases. The nonhydroxylated fatty acids are composed of predominantly *iso*-methyl branched types, with *iso*-$C_{15:0}$ acid predominating. The DNA G + C content is 43–44 mol% (Coykendall et al. 1980).

THE CURRENT STATUS OF SPECIES THAT PREVIOUSLY BELONGED TO THE GENUS *BACTEROIDES*

The emphasis now is to develop taxonomic schemes that reflect 'natural' or 'evolutionary' relationships among bacteria which has led to re-examination of many taxa that only superficially resemble the generic description of type species. Members of the genus *Bacteroides* have been subjected to rigorous chemotaxonomic analysis and the results from these studies have been largely confirmed by molecular systematic analysis. Thus, the more restricted definition of the genus *Bacteroides* and the proposal of *Prevotella* and *Porphyromonas* have been borne out by data derived from comparative sequence analysis of 16S rDNAs (see Figure 2), whereas others that have been excluded from the genus have been substantiated by these tests (see reviews by Shah and Collins 1983; Shah et al. 1997; Olsen and Shah 2003). The current status of some of these taxa is described below.

Bacteroides ureolyticus and *Bacteroides gracilis*

B. ureolyticus is a nonfermentative, nonpigmented species that characteristically 'pits or corrodes' the agar around the colonies. It was first described by Henriksen (1948) in clinical specimens and later by Eiken (1958) who isolated 21 strains from abscesses, principally from the buccal region, and assigned them to the genus *Bacteroides* as *Bacteroides corrodens*. Khairat (1967) cultivated a similar organism from blood cultures after tooth extraction and also three strains phenotypically similar from the gingival crevice. Reinhold (1966) found it in abscesses and Schröter and Stawru (1970) in diseased tonsils. It was renamed *B. ureolyticus* to clarify the distinction between it and *Eikenella corrodens*, an aerobic and facultatively anaerobic, carbon dioxide-dependent organism that also forms 'corroding' colonies. The two were often confused in early reports (Jackson and Goodman 1978). This species was subsequently shown to share few biochemical and chemical properties with the genus *Bacteroides* sensu stricto (see Shah and Collins 1983) and was excluded from the redefined genus. *B. gracilis* shares a number of common properties with *B. ureolyticus* in that it is nonpigmented, asaccharolytic, microaerophilic, and colonies often show pitting or corroding growth indistinguishable from that of *B. ureolyticus*. However, it is oxidase-negative and does not produce urease, although some strains reduce nitrate to nitrite (Tanner et al. 1981). Chemotaxonomic analyses, DNA–rRNA hybridization, and 16S rRNA sequence analysis have shown that both species belong to the genus *Campylobacter* and *B. ureolyticus* has been formally reclassified in this genus (Vandamme et al. 1995).

Bacteroides praeacutus

Strains have been isolated from human feces and from clinical specimens. *B. praeacutus* differs from other species of *Bacteroides* in being motile by means of peritrichous flagella and differ so markedly in biochemical and chemical properties (e.g. its G + C content is 28 mol%) from other members that it was excluded from the emended description of the genus *Bacteroides* (Shah and Collins 1983) and was reproposed in the genus *Tissierella*, as *Tissierella praeacuta*. The 16S RNA gene sequence has shown that this species is synonymous with *Clostridium hastiforme*.

Bacteroides pneumosintes

B. pneumosintes is a very small bacillus that is filterable through Berkfeld V and N filters and is unreactive in most conventional bacteriological tests. It was described by Olitsky and Gates (1921, 1922) in nasopharyngeal washings from patients in the 1918 influenza pandemic and called *Dialister pneumosintes*. These authors thought that it was a significant pathogen. It has since been isolated from normal persons, but it may be concerned in secondary infections of the respiratory tract, including lung abscesses, and in metastatic brain abscesses. Long considered to be outside the generic description of *Bacteroides* (see Shah and Collins 1983), the genus *Dialister* was revived by Moore and Moore (1994) to accommodate this species. More recently, it was shown by Willems and Collins (1995a) that these microorganisms

belong to the *Sporomusa* sub-branch of the *Clostridium* subphylum.

Bacteroides nodosus

B. nodosus is a significant pathogen, causing foot rot in sheep (Egerton and Parsonson 1966) and possibly also in goats and cattle (Wilkinson et al. 1970). The hoof seems to be its natural habitat. The cells are irregular with terminal enlargements, especially in smears prepared directly from lesions. It is strongly proteolytic and will digest powdered hoof in vitro. The DNA G + C content is 45 mol%. It was reclassified in a new genus, *Dichelobacter*, as *Dichelobacter nodosus*.

Bacteroides putredinis and *Bacteroides microfusus*

Despite being nonfermentative, some strains of *B. putredinis* grow in a glucose broth to produce cells that are either straight or curved with rounded ends. Some cells produce swellings at one end, but spores have not been detected. Strains are proteolytic and some may digest cooked meat. *B. putredinis* produces fibrinolysin and may be isolated from feces, abdominal and rectal abscesses, cases of acute appendicitis, and foot rot in sheep. It has been reported from the human oral cavity. It shares very few characters with members of the genus *Bacteroides* and recent 16S rRNA sequence analysis (Paster et al. 1994) has shown this species to be most closely related to *Rikenella microfusus* (formerly *Bacteroides microfusus*). Both species show close affinity to the genus *Cytophaga*.

Bacteroides ochraceus

This species was shown to be distantly related to the genus *Bacteroides* and to contain several centers of variation. These have now been assigned to the genus *Capnocytophaga* as *Capnocytophaga ochracea* (the type species), *Capnocytophaga canimorsus*, *Capnocytophaga cynodegmi*, *Capnocytophaga gingivalis*, *Capnocytophaga granulosa*, *Capnocytophaga haemolytica*, and *Capnocytophaga sputigena*.

Bacteroides succinogenes and *Bacteroides amylophilus*

Both these species are associated with the rumen and are biochemically and chemically unrelated to the genus *Bacteroides*. They have been reclassified in the genera *Fibrobacter* and *Ruminobacter*, respectively.

Bacteroides furcosus, *Bacteroides termitidis*, *Bacteroides multiacidus*, *Bacteroides hypermegas*

These species share few properties with the genus *Bacteroides* and have been reclassified as *Anaerorhabdus furcosus*, *Sebaldella termitidis*, *Mitsuokella multiacidus*, and *Megamonas hypermegas* (see review, Shah and Gharbia 1997; Shah and Collins 1986). 16S rRNA sequence analysis has shown that some of these genera, such as *Sebaldella* and *Anaerorhabdus*, show a close affinity with gram-positive taxa of the *Clostridium* subphylum. The genera *Mitsuokella* and *Megamonas* cluster with *Selenomonas* and *Pectinatus*.

Prevotella zoogleoformans and *Prevotella heparinolyticus*

These species are classified in the genus *Prevotella* based on their phenotypic properties, but 16S rRNA sequence data suggest that they are distinct lineages (see Olsen and Shah 2003).

ANTIBIOTIC RESISTANCE

Gram-negative anaerobes are sensitive to metronidazole, but are resistant to aminoglycosides, quinolones, and monobactams. Until a few years ago, most members of the Bacteroidaceae were susceptible to antimicrobial agents such as clindamycin, chloramphenicol, erythromycin, and tetracyclines. Over the years antibiotic resistance has been increasingly reported. *Bacteroides* spp. have been shown to acquire resistance rapidly to most beta-lactam antibiotics (minimal inhibitory concentration usually exceeds 16 mg/l). This is associated with the production of broad spectrum beta-lactamases (Olsson et al. 1979). In 1955, the first cases of resistance to penicillin were described (Garrod 1955). A noninducible cephalosporin was isolated from strains of *B. fragilis* and to date 93 percent of resistant strains produce β-lactamases. Similar patterns were reported among *B. ovatus*, *B. vulgatus*, *B. thetaiotaomicron*, and *B. distasonis*. Lower incidences of β-lactamases (40–60 percent) have been reported for *Prevotella* and *Porphyromonas*. Pencillinases and cephalosporinases were reported from *P. disiens*, *P. buccae*, *P. oris*, *P. melaninogenica*, and *P. asaccharolytica*. Most β-lactamases produced are constitutive cephalosporinases, although penicillinases and enzymes that hydrolyze cefoxitin and imipenem have been described. Both chromosomally mediated and plasmid-mediated penicillin resistance have been described, with the production of at least six different β-lactamase types.

Resistance to chloramphenicol is mediated by either a nitroreductase or an acetyltransferase. Although both mechanisms have been observed among *Bacteroides*

spp., the acetyltransferase activity is transferable among *Bacteroides* spp. However, the rate of transmission in vivo is apparently low since chloramphenicol resistance is detected in less than 1 percent of isolates. This may be due to the infrequent use of this potentially toxic drug (Jenkin 2001).

Clindamycin is one of the most widely used antimicrobial drugs in the treatment of anaerobic infections. Recent studies suggest that resistance to clindamycin in *B. fragilis* is 5–20 percent, less than 5 percent in other *Bacteroides* spp., and 10 percent for *Prevotella* and *Porphyromonas* species. Resistance is mediated by an RNA methylase that alters the 50S subunit of ribosomal RNA and modifies the site of action of the drug. Resistance is due to the transfer of transposable elements, such as Tn*4351* and Tn*4400* (Shoemaker et al. 1985).

Metronidazole resistance in *Bacteroides* spp. is associated with plasmids that have been shown to transfer to other species via conjugation. Despite the low incidence of resistance to metronidazole, the fact that such resistance is transferable suggests the possibility of increased resistance in the future.

Tetracycline resistance in *Bacteroides* isolates was uncommon, but today all clinical isolates of *Bacteroides* spp. are resistant to tetracycline due to the spread of conjugative elements throughout *Bacteroides* spp. Increased use of tetracyclines for the treatment of periodontal diseases and other oral infections is largely responsible for the spread of resistance among *Prevotella* and *Porphyromonas* spp. Such resistance is mediated by chromosomally expressed ribosomal protection mechanisms. In *Bacteroides* and *Prevotella* spp., conjugative elements harboring the genetic determinants *tetQ* and *tetM* were reported (Salyers and Shoemaker 1995).

Resistance to macrolides is usually plasmid or transposon mediated and is related to lincosamide resistance and results in the dimethylation of the 50S ribosomal subunit. The most frequently detected genes responsible for such activity in *B. fragilis*, *B. ovatus*, and *B.vulgatus* are *ermF* and *ermFS* (Garcia-Rodriguez et al. 1995).

MOLECULAR ANALYSIS

Most of the early work on the genetics of the Bacteroidaceae focused on the genus *Bacteroides*. This is due in part to the fact that members of this genus are among the most oxygen tolerant of all obligate anaerobes, they are not nutritionally fastidious and their growth rates are 1–3 h per generation time. They harbor conjugative plasmids that are transferable to *Escherichia coli* and other members of the Bacteroidaceae. The fact that *Bacteroides* spp. are opportunistic pathogens, *B. fragilis* accounting for almost half of all human anaerobic infections, has promoted interest in its genetics.

The physical and genetic map of *B. fragilis* was compiled using the chromosome of strain YCH46 (Kuwahara et al. 2002). It is a single circular DNA molecule of 5.3 Mb. The physical map was constructed by comparative analysis of the data generated from cross-southern hybridization, partial restriction digest, pulse field gel electrophoresis, and linking clone analysis. The map revealed six rRNA operons (*rrn* loci). The location of ten genes including *recA*, *rprX*, and *tuf* were identified. The loci for the enzymes ATP-synthase, fructanase, neuraminidase, and glutamine synthetase, as well as *ccrA* encoding class beta-lactamases were described. It is envisaged that the localization of genes across the physical map can be linked to the data currently being annotated for the *B. fragilis* and *B. thetaiotamicron* genomovars and will play a significant role in detecting reorganizational events directing the emergence of species (Xu et al. 2003).

Many *Bacteroides* strains have cryptic plasmids (3–6 kb) that are mobilized by conjugative elements. However, clindamycin and erythromycin determinants are harbored on plasmids isolated from *B. ovatus*. Tetracycline resistance determinants were isolated downstream from these genes. However, the gene products of these tetracycline resistance elements are functional only under aerobic conditions.

Conjugative transposons are elements that integrate within the bacterial chromosome but, unlike transposons, do not duplicate the target site. Furthermore, a circular intermediate structure is formed during excision and transfer. *Bacteroides* conjugative transposons usually carry the tetracycline determinant *tetQ* (Salyers and Shoemaker 1995). Some conjugative transposons carry erythromycin-resistance genes that also confer resistance to clindamycin. However, cryptic conjugative elements were detected. Interestingly, strains expressing multiple resistance carry conjugative transposons, which may explain the rapid and widespread occurrence of such resistance among members of the genus *Bacteroides*. In many cases, conjugative transposons can also mediate the excision and mobilization of coresident plasmids.

This transfer is stimulated by the exposure of donors to low concentrations of tetracycline prior to conjugation. This was shown to increase the frequency of transfer by 1 000–10 000-fold. Clindamycin was also shown to stimulate the rate of transfer. *Bacteroides* conjugative elements have been shown to transfer resistance to *Prevotella* and *Porphyromonas* spp. in the presence of tetracycline.

Conjugative transposons are extremely stable and, unlike antibiotic resistance plasmids, are maintained in *Bacteroides* strains in the absence of selection through exposure to antibiotics. Several genes from *B. fragilis*, such as *recA* and sialidases, were expressed in *E. coli*. Therefore, plasmids isolated from *B. fragilis* and *B. thetaiotaomicron* that harbor antibiotic markers were integrated into *E. coli*-based shuttle vectors to construct new systems for the cloning and expression of genes of members of the Bacteroidaceae.

P. gingivalis is an intensively studied species of the genus *Pophyromonas* (Shah 1993) and sufficient genes from a range of strains have been sequenced to enable an insight into the structure of its genome when compared to the sequenced chromosome of strain W83. Once the process is completed, it will have a major impact on resolving the molecular basis of pathogenesis within this species. Early attempts to clone and express surface-associated proteins failed to yield mature proteins and resulted in the rearrangement of the cloned fragments. Random cloning and selection of recombinant was replaced with screening with degenerate primers, constructed N-terminal sequences or conserved motifs of similar proteins. The amplified fragments were sequenced to ascertain their identity and used to screen gene libraries and clinical isolates and better results were obtained. Using this approach, the structure and distribution of the fimbriae-encoding gene was determined (Hamada et al. 1994). Several sequences of the major extracellular proteinase have been reported and deposited in the databank. However, the biochemical and physiological studies support the view that all the extracellular proteolytic activity of *P. gingivalis* is associated with cysteine proteinases (Pavloff et al. 1995). Furthermore, the results of cloning and molecular analysis have revealed that the proteinase forms a complex association with adhesin molecules on the bacterial surface and is responsible for its attachment to erythrocytes.

The metalloenzyme superoxide dismutase (SOD) of *P. gingivalis* has the highest known activity of any *Porphyromonas* or *Prevotella* species. It was reported recently that an increase in temperature from 37 to 39°C resulted in an increase in SOD messenger RNA and a three-fold rise in SOD activity. Molecular analysis revealed that the enzyme is transcribed as single apoprotein monomers, but post-transcriptional modification yields two minor Fe-containing SOD isoenzymes (when cell extracts are maintained anaerobically) and a major Mn-containing SOD (when cells are aerated), both of which are encoded by a single copy on the chromosome, which is a unique feature.

The genes for several unrelated enzymes have been deposited in databases, but the significance of these to the biology of *P. gingivalis* has not yet been clarified. These include a methylase-encoding gene, heat shock protein operon, an insertion element, genes encoding an alkaline phosphatase, and methylmalonyl-CoA mutase (see review by Gharbia et al. 1995).

A unique molecular structure among bacteria was revealed through the study of an adhesin gene from *P. loescheii*. The gene, referred to as *plaA*, possesses two overlapping reading frames which encode an 89 kDa polypeptide (Manch-Citron et al. 1992). The leader sequence and 28 residues of the N-terminus are encoded within frame 1 and a second reading frame is initiated on the complementary strand. Sequencing results and confirmation using polymerase chain reaction (PCR) amplification of several gene fragments strongly suggest a frameshift within *plaA*, which represents an uncommon phenomenon among bacteria. Such a mechanism enables a single gene to encode several proteins, fusion protein transcription, and truncated gene products.

BACTEROIDES, *PREVOTELLA*, AND *PORPHYROMONAS* IN THE NORMAL FLORA

In humans

Gram-negative anaerobic bacilli are a major component of the normal commensal flora of the mucous membranes of the mouth, lower gastrointestinal tract, and vagina. Eggerth and Gagnon (1933) recognized their importance in the fecal flora and Rosebury (1962) stressed their normal occurrence at all three sites. The species of gram-negative anaerobic bacilli found at the three sites form distinct populations that account for the majority of endogenous opportunistic infections.

ORAL MICROFLORA

The mouth does not have a uniform bacterial population. The gingival crevice and subgingival plaque are the principal sites of colonization with gram-negative anaerobic bacilli (Socransky and Manganiello 1971; Hardie and Bowden 1974). Gram-negative anaerobic bacilli are rarely detected in infants before the eruption of teeth. As dentition develops during childhood, the frequency of colonization increases (Sutter 1984). Kelstrup (1966) found that the isolation rate of black-pigmented species rose from 18 percent in children aged 5 years to 70 percent at 16 years. *Prevotella* spp. are present in large numbers in the gingival crevice and subgingival plaque of all healthy adults. Studies have shown that they represent 12 percent (Slots 1977) to approximately 30 percent (Williams et al. 1976; Newman et al. 1978) of the cultivable flora. However, they constitute only approximately 4 percent of the cultivable flora of supragingival plaque in normal subjects (Gibbons et al. 1964), although in institutionalized subjects the proportion may reach 17 percent (Loesche et al. 1972). In the presence of gingivitis and peridontitis their numbers, particularly those of *P. gingivalis* and *P. intermedia*, increase.

Pigmented species were first described in studies of the microflora of mucous membranes, in particular, of the gingival mucosa (Oliver and Wherry 1921). They are useful marker species for the anaerobic flora of the gingival crevice (Holbrook et al. 1978). Pigmented strains constitute 4–6 percent of the cultivable flora of the normal gingival crevice (Gibbons 1974; Williams et al. 1976) and 5–6 percent of the plaque flora from institutionalized subjects (Loesche et al. 1972).

Pigmented *Prevotella* spp. can be isolated from almost all subjects and account for 10–20 percent of the gram-negative anaerobic bacilli, whereas the nonpigmented species account for about 35 percent (Loesche et al. 1972; Gibbons 1974; Duerden 1980c). Species of *B. fragilis* are not part of the normal gingival flora (Hardie 1974).

Gingival strains of Bacteroidaceae are often nutritionally demanding and may be difficult to maintain in pure culture on solid media. Many species are nutritionally interdependent and will grow only in mixed culture, in which satellitism may be demonstrated. Growth is often improved by the addition of 5–10 percent CO_2 in the anaerobic atmosphere (Watt 1973; Stalons et al. 1974) and recognized growth factors include metal ions (Caldwell and Arcand 1974) and hemin (Gibbons and MacDonald 1968; Gilmour and Poole 1970). Most *Prevotella* and *Porphyromonas* spp. also require menadione (vitamin K, Lev (1959)) or its precursors (Robins et al. 1973) and succinate (Lev et al. 1971).

GASTROINTESTINAL MICROFLORA

Gram-negative anaerobic bacilli are generally the most numerous bacteria in the normal flora of the gastrointestinal tract, similar in numbers to the bifidobacteria. The genus *Bacteroides* forms the majority of the cultivable species (Drasar and Hill 1974). The anaerobic intestinal flora develops early in life. In breast-fed infants, bifidobacteria predominate and gram-negative anaerobic bacilli are present in the first week of life only in about 20 percent of such infants. However, more than 60 percent of bottle-fed infants are colonized by *Bacteroides* spp. in the same period. At weaning, the numbers of bifidobacteria decrease, whereas the numbers of *Bacteroides* rise to outnumber bifidobacteria by 3:1 (Long and Swenson 1977). Rotimi and Duerden (1981) reported a heavy growth of *Bacteroides* from 75 percent of 16 infants 5–6 days old who were breast fed, but received supplementary bottle feeds. Obligate anaerobes are seldom found in the normal stomach, duodenum, jejunum, or proximal ileum. *Bacteroides* spp. and *Bifidobacterium* spp. begin to appear only in the distal ileum (Finegold 1977) and they form a major part of the cecal and fecal flora. Viable counts of *Bacteroides* yield 10^{11} organisms per gram wet weight of feces and cecal contents (Drasar 1967; Finegold et al. 1975). The proportion of *Bacteroides* spp. in the fecal flora differs in subjects from different countries and is related to the type of diet. They are found in greater numbers in subjects who consume a mixed western diet that contains comparatively large amounts of fat and stimulates the production of a large volume of bile. Fewer *Bacteroides* spp. are found in subjects from developing countries in Africa and Asia, and from Japan, who consume a mainly vegetarian diet. Gram-positive anaerobes and enterococci are the predominant fecal organisms in these subjects. However, subjects in developed countries who change to a vegetarian diet do not convert their fecal flora to a gram-positive predominance and retain their *Bacteroides* organisms (Drasar 1974).

Some 80 percent of fecal gram-negative anaerobic bacilli are members of the genus *Bacteroides*. The most common species in most subjects are *B. vulgatus*, *B. thetaiotaomicron*, and *B. distasonis*. *B. eggerthii* is found regularly, but *B. fragilis* forms only a small proportion of the bacteroides in the normal fecal flora (Werner 1974; Finegold et al. 1975; Moore and Holdeman 1975; Duerden 1980a). Holdeman et al. (1976) identified 1 442 isolates belonging to 101 species from 25 specimens of feces from three men; *B. vulgatus*, *B. thetaiotaomicron*, and *B. distasonis* were three of the five most prevalent bacterial species, representing 11.8, 8.9, and 6.0 percent of isolates, respectively, whereas *B. fragilis* represented only 0.3 percent. They also found that the proportion of *B. thetaiotaomicron* isolates rose under stressful conditions. Asaccharolytic species of the Bacteroidaceae form a consistent part of the normal fecal flora, but are present in much smaller numbers than *Bacteroides* (Werner et al. 1971). The most commonly recognized species is *P. asaccharolytica* and the lower gastrointestinal tract is probably the primary habitat of this species. Nonpigmented asaccharolytic species are also present in quite small numbers. They grow slowly to form only small colonies and are difficult to detect.

The gram-negative anaerobic bacilli play an important part in the physiological activities of the large intestine. They are responsible for much of the metabolism of bile salts and bile acids. *Bacteroides* spp. and several clostridia produce enzymes that deconjugate bile salts under conditions of low E_h, and they reduce cholic acid to deoxycholic acid. This is important in the enterohepatic circulation of bile salts. They may also be implicated in the production of carcinogens from bile acids. *Bacteroides* spp. produce dehydrogenases and dehydroxylases that convert bile acids into aromatic compounds and eventually to substituted cyclopentaphenanthrenes, which are known to be carcinogens. Differences in the incidence of colonic carcinoma in various countries are associated with the type of diet consumed and with the relative numbers of gram-negative anaerobic bacilli in the feces (Drasar and Hill 1974).

Several studies have been conducted to provide a comparative analysis of the anaerobic microbiota of the gastrointestinal tract in infants and adults. This is mainly carried out by nonculturable 16S rRNA amplification and random sequencing or hybridization (see Rigottier et al. 2002).

VAGINAL MICROFLORA

The role of the Bacteroidaceae in the normal vaginal flora has been the subject of controversy. The vagina is

not a single environment. The flora of the lower vagina is a mixture of organisms from the vagina with others from the perineum and introitus, whereas the flora of the cervix and fornices more closely represents the true vaginal flora. Moreover, the environment is not constant. The state of the mucosa and secretions changes with age, with each menstrual cycle, and with pregnancy (Hurley et al. 1974).

Gram-negative anaerobic bacilli are common, but not universal, commensals of the cervix and vaginal fornices. The presence of Bacteroidaceae in the vagina was reported first by Burdon (1928). He isolated *P. melaninogenica* from 28 of 35 normal women.

Bacteroides spp. were isolated from cervical cultures in 57 percent (Gorbach et al. 1973) and 65 percent (Sanders et al. 1975) of normal women and from the posterior vaginal fornix in 65 percent and 100 percent of two groups of 20 normal women (Duerden 1980b; Wilks et al. 1984). However, other workers have found them considerably less often: 8.6 percent of 246 preoperative gynecological patients (Neary et al. 1973); 4.6 percent of 500 women attending a family planning clinic; 5 percent of 200 patients attending a gynecological outpatient clinic; 5.4 percent of 280 pregnant women (Hurley et al. 1974); four of 100 pregnant women; and one (4 percent) of 23 normal women in a quantitative study by Taylor et al. (1982). Some of these differences may reflect differences between populations, but most are probably attributable to different methods of investigation and, in particular, to differences in sampling methods and in anaerobic technique. In studies with good anaerobic methods, isolation rates from normal women have been generally higher in qualitative studies (approximately 60 percent, see above) than in quantitative studies – 41 percent (Masfari et al. 1986), 34–40 percent (Bartlett and Polk 1984), 34 percent (Hammann 1982) – in which small numbers of anaerobes may not have been detected. In quantitative studies, mean viable counts of *Bacteroides* spp. in those normal women from whom gram-negative anaerobic bacilli were isolated varied from 10^6 colony-forming units (cfu)/g (Masfari et al. 1986) to $10^{8–9}$ cfu/g or ml (Bartlett and Polk 1984; Wilks et al. 1984) of vaginal secretions. Few consistent variations have been detected in sequential samples taken during the menstrual cycle. Bartlett and Polk (1984) and Wilks et al. (1984) both found that levels of aerobes were higher during the first week of the cycle, but there was little change in the levels of anaerobes. However, *Bacteroides* spp. are reported to disappear during pregnancy and return soon after delivery (Hite et al. 1947; Willis 1977).

The species of Bacteroidaceae isolated in early studies of the vaginal flora were not identified. When detailed identification methods have been used, the predominant species have been members of *Prevotella* spp. *P. bivia* is the most common species isolated in most studies. *P. disiens*, *P. intermedia*, and *P. melaninogenica* are also common. *P. asaccharolytica* can be isolated in smaller numbers. The presence of significant numbers of *Bacteroides* organisms, and in particular of *B. fragilis*, indicates some pathological change in the genital tract.

In animals

Gram-negative anaerobic bacilli are part of the normal flora of intestinal contents and feces in many species of animals from invertebrates to humans. They are an important component of the flora of two specialized gastrointestinal structures, the rumen of ruminant animals and the cecum of poultry.

Species that are now no longer considered as *Bacteroides* spp. are found in large numbers in the rumen: *Fibrobacter succinogenes*, *Ruminobacter amylophilus*, and *P. ruminicola*. *F. succinogenes* is found in most ruminants and attains a viable count of approximately 0.5×10^8 cfu/ml, about 8.5 percent of the total viable count. It is actively cellulolytic and is important in the digestion of cellulose. It also ferments glucose, cellobiose, and several other carbohydrates, producing succinic acid (Hungate 1950). *R. amylophilus* and *P. ruminicola* are not cellulolytic. They are active in the digestion of starch and other carbohydrates. *R. amylophilus* occurs sporadically, but when present may be the predominant starch digester and constitute 10 percent of the total bacteria (Hamlin and Hungate 1956). The fermentative activity of *P. ruminicola* is more varied. It is regularly present and constitutes 6–19 percent of the total viable count.

The rumen bacteria are essential for the nutrition of ruminants. The energy content of the feedstuff is made available to the animal in the form of volatile fatty acids, particularly acetic, butyric, and propionic acids, produced by the bacterial fermentation of cellulose and other carbohydrates. The acids are absorbed through the rumen wall and metabolized by the animal. The removal of these acid products is essential for the continuation of fermentation. In addition, microbial protein constitutes a major part of the ruminants' protein source. Nitrogenous components of the feed are converted to microbial protein during growth and multiplication of the rumen bacteria, which contain approximately 65 percent of protein. In the distal parts of the intestine, dead bacterial cells are digested and provide protein for the animal (Hungate 1966).

In poultry, the cecum is highly developed and has an important role in digestion and absorption. Gram-negative anaerobic bacilli are found in large numbers (approximately $10^{8–9}$/g) in the cecal contents. The most common species is unique to this site – *Megamonas hypermegas* – which ferments a variety of carbohydrates (Barnes and Goldberg 1968a, b).

ANTIMICROBIAL SUSCEPTIBILITY

Susceptibility towards different agents

A number of multicenter studies have been conducted in the United States, Europe (including France, Germany, Great Britain, Sweden, Italy, and Spain), Japan, Australia, Israel, and South Africa in order to survey the in vitro antimicrobial susceptibility of anaerobic bacteria (Falagas et al. 2000). An alarming and gradual increase in resistance rates to several antibiotics have been reported in *Bacteroides* and other anaerobes. These can be classified in four categories according to their effect on the genus *Bacteroides* sensu stricto. The first group is active against almost all (>99 percent) clinical *Bacteroides* isolates and includes metronidazole, chloramphenicol, imipenem, and meropenem. Isolates of *B. fragilis* resistant to this group of antibiotics have been reported sporadically. Furthermore, *B. fragilis* isolates resistant to multiple agents such as metronidazole, imipenem, and amoxicillin/clavulanic acid have been detected (Turner et al. 1995). The second group of agents, which is active against most (95–99 percent) *B. fragilis* isolates comprises the β-lactam/β-lactamase inhibitor combination drugs, i.e. ticarcillin/clavulanic acid, piperacillin/tazobactam, and ampicillin/sulbactam. Many *Bacteroides* strains produce β-lactamases that hydrolyze most β-lactams and addition of β-lactamase inhibitor increases the in vitro activity of β-lactams. *Bacteroides* species other than *B. fragilis* are more apt to be resistant to β-lactam/β-lactamase inhibitor combinations than *B. fragilis* (Snydman et al. 1996). The third group of agents that is frequently active against bacteroides includes clindamycin and cephalosporins such as cefoxitin, cefotetan, ceftizoxime, and cefmetazole. A lower resistance rate to these agents has been observed in *B. fragilis* compared to other bacteroides and there is also considerable interspecies variability in the resistance rate of these drugs between different bacteroides other than *B. fragilis*, as reflected in the susceptibility patterns of *B. fragilis* species isolated from bacteremia (Aldridge et al. 2003). Also among diseased animals (cattle, sheep, goats, horses, pigs, dogs, cats, rodents, zoo animals), resistant strains among *Bacteroides*, *Prevotella*, *Porphyromonas*, and *Fusobacterium* belong mainly to the *Bacteroides* sensu stricto (Even et al. 1998). Among the *Bacteroides*, the highest resistance rates are observed for the following organisms/drug combinations: for clindamycin/*B. distasonis* and *B. ovatus*; for cefoxitin/*B. thetaiotaomicron*, *B. distasonis* and *B. uniformis*; for ampicillin-sulbactam/*B. distasonis*, *B. ovatus*, and *B. uniformis*; and for trovafloxacin/*B. vulgatus* (Aldridge et al. 2001). With few exceptions all agents were highly active against isolates of *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Peptostreptococcus*. The efficacy of cefoxitin in *Bacteroides* is low with only 43–46 percent of the strains isolated being susceptible (Oteo et al. 2000; Oteo-Iglesias et al. 2002). Fourthly, monobactams, aminoglycosides, and the early quinolones have poor activity against all or most groups of anaerobic bacteria (Goldstein et al. 1993). More recently developed fluoroquinolones, such as trovafloxacin, have improved anti-anaerobic activity. There has been a significant increase in resistance to new fluoroquinolones from 0 percent in 1998 to 12 percent in 2001 (Oteo-Iglesias et al. 2002).

Penicillin, including amoxicillin, is only rarely active against the bacteroides, but is frequently active against *Prevotella* and *Porphyromonas* species (Falagas and Siakavellas 2000). A gradual increase in the rate of resistance to penicillin has been reported over the last 20 years (Niederau et al. 1980; Sedallian and Debrueres 1987; Olsvik and Tenover 1993). Aldridge et al. (2003) found that all blood isolates of bacteroides tested from 1987 to 1999 by the same NCCLS-recommended broth microdilution method were resistant to penicillin G, and 22 percent were resistant to clindamycin. A high prevalence of resistance to clindamycin, reaching 49–56 percent of the isolates in bacteroides has been reported (Oteo et al. 2000; Oteo-Iglesias et al. 2002), while a high incidence of clindamycin (50 to 70 percent) and cefoxitin (31 to 65 percent) resistance was found in *Bacteroides* spp. other than *B. fragilis* (Teng et al. 2002). Blood isolates may be less susceptible to antibiotics than isolates from intraabdominal, obstetric-gynecologic, and other sources of clinically important anaerobes (Aldridge et al. 2001). Beta-lactamase-positive strains may be susceptible to agents such as imipenem and chloramphenicol (Uraz and Turkmen 1999).

There is a synergistic effect between gentamycin and penicillin, clindamycin, or metronidazol against some *Bacteroides* isolates (Brook et al. 1984). Clindamycin, rifampin, nalidixic acid, ticarcillin, erythromycin, and spectinomycin show synergy with metronidazole against less than 50 percent of *B. fragilis* strains (Ralph and Amatnieks 1980). Furthermore, in vitro synergy between trovafloxacin and cefoperazone or ceftazidime has been observed against a small minority of *Bacteroides* spp. (Falagas and Siakavellas 2000).

Mechanisms of resistance

In general, β-lactamase production is the most important cause of β-lactam resistance in anaerobic gram-negative bacteria. All *Bacteroides*, except some strains of *B. distasonis*, produce β-lactamase (Nord 1986; Appelbaum 1992; Rasmussen et al. 1997). Beta-lactamase is also produced by about half of *Prevotella* spp. and about 20 percent of *Porphyromonas* spp. (Falagas and Siakavellas 2000). Bernal et al. (1998) reported that 20 percent of strains identified as *P. intermedia* were β-lactamase-producing, as were 72 percent of *P. nigrescens*.

Carbapenemases have been reported from Japan (Edwards and Greenwood 1996; Bush 1998). Other mechanisms of antibiotic resistance in anaerobes include alteration of penicillin-binding proteins and the blockage of antibiotic penetration to the active site by modification of outer membrane pores (Wexler and Halebian 1990). Tetracycline resistance in anaerobic bacteria is related to blocked antibiotic uptake (Tally et al. 1984). In clindamycin resistance, nonenzymatic alteration of the target site is the usual mechanism (Dalmau et al. 1997), while the rare resistance generally observed for metronidazole is due to decreased uptake of antibiotic and decreased nitroreduction of the compound (Appelbaum 1992). Enhanced pathogenicity has been demonstrated in susceptible strains of *Bacteroides* subjected to low doses of metronidazole (Diniz et al. 2003). Mutational events in the gyrA quinolone resistance-determining region seem to contribute to quinolone resistance in *Bacteroides* spp. (Oh et al. 2001).

PATHOGENICITY

Members of the genera of *Bacteroides*, *Prevotella*, and *Porphyromonas* are part of the normal commensal flora of man and animals. A large number of studies have indicated that the most important pathogens of this group are *B. fragilis* (intestinal) and *P. gingivalis* (oral), consequently most investigations have been focused on these two species.

Environmental factors

Bacterial virulence factors can be modified by a number of environmental parameters such as nutrients, oxygen tension, etc. In the oral cavity, the virulence of *P. intermedia* and *P. nigrescens* was shown to decrease in the presence of glucose, whereas no such effect was observed on *P. gingivalis* (Saito et al. 2001). *P. gingivalis* has an obligate requirement for heme or selected heme- or Fe-containing compounds, however, the regulation of the heme biosynthetic genes remains puzzling (Roper et al. 2000). The influence of heme on the expression of several putative virulence factors in this bacterium has been demonstrated. A 35-kDa protein is one of the hemin-binding proteins in *P. gingivalis* and its binding ability is important for expression of virulence (Shibata et al. 2003). Isolates of *P. gingivalis*, having a low requirement for iron, are likely to have a higher potential for initiating periodontal infections (Grenier et al. 2001).

Microorganisms adapt to environmental cues by turning on and off the expression of virulence genes which allows for optimal growth and survival within different environments (Forng et al. 2000). When *P. gingivalis* in human dental plaque from periodontitis patients were stressed in vitro by a temperature increase of 5°C, a rapid rise occurred in the mRNA associated with the molecular chaperons (*htpG*, *dnak*, *groEL*), SOD (*soda*), and gingipain (*rgp-1*) genes (Shelburne et al. 2002). Furthermore, the levels of stress gene transcription for dnak and htpG were significantly elevated at diseased sites, and grEL gene transcription increase approached statistical significance. There were also correlations between probing depth and increased transcription of *groEL*, *htpG* and *rgp-1* and between disease status and elevated expression of *dnaK* and *htpG*.

Wu et al. (2002) suggested that knockout of *ivi* genes reduced the ability of mutated *P. gingivalis* to survive and cause infection compared to the wild-type strain at the site of infection. Mutants also had lower capacity for invasion.

In a study by Liu and Fletcher (2001a) the *recA* promoter was found to be transcriptionally active during active *P. gingivalis* infection in a murine host. The expression of the *recA* gene is responsive to several environmental signals, but is not regulated by a DNA damage-inducible SOS-like regulatory system (Liu and Fletcher 2001b). The *recA* downstream gene *vimA* (virulence-modulating gene) plays an important role in virulence modulation of *P. gingivalis* W83, possibly representing a novel post-transcriptional or translational regulation of virulence factors in this organism (Abaibou et al. 2001).

Methyl mercaptan is highly toxic and its presence in the periodontal pocket suggests that it could be involved in progression of periodontal disease. *P. gingivalis* is considered as the most potent producer of this substance. Only 7.7 percent of mice infected with strain W83 of *P. gingivalis* survived 4 days after subcutaneous injection, whereas 36 percent of the mice survived injection with a mutant strain deficient in methyl mercaptan production (Nakano et al. 2002). A marked decrease in the formation of methyl mercaptan from L-methionine and decreased virulence was seen in the mutant compared to the wild-type strain (Yoshimura et al. 2000).

Lipopolysaccharide

LPS has been identified as a major factor in bone resorption. Based on the role of IL-1 beta in *P. gingivalis* LPS-induced bone resorption, it was suggested that it may be caused by enhancing osteclastogenesis, not by increasing the osteoclast resorbing activity (Chiang et al. 2002). *P. gingivalis* LPS-induced bone resorption and IL-6 production in the gingival tissue was inhibited with antibody towards CD14 which is a significant receptor for LPS on human gingival fibroblasts and gingival epithelial cells (Wang et al. 2002). LPS from *P. intermedia* participated in periodontal tissue destruction and alveolar bone resorption, but in addition inhibited bone

formation (Pelt et al. 2002). LPS derived from periodontal pathogens also cause imbalance in the regulation of plasminogen activator and plasminogen activator inhibitor in human gingival fibroblasts (Xiao et al. 2001). This may contribute to the destruction of periodontal connective tissue through dysregulated pericellular proteolysis. Urokinase-type plasminogen activator receptor (uPAR) presenting at the cell surface with glycosylphosphatidylinositol anchor is a key component in the plasminogen activator-plasmin system and plays a critical role in extracellular matrix degradation. An increase of the uPAR level by LPS may be important in the progression of periodontal diseases through pericellular proteolysis (Ogura et al. 1999).

P. gingivalis LPS is both agonist and antagonist for p38 mitogen-activated protein kinase activation. LPS from this organism may therefore selectively modify the host response as a means to facilitate colonization (Darveau et al. 2002).

B. fragilis LPS effectively stimulated macrophage inflammatory protein-2 (MIP-2) expression even in the absence of functional TLR4 in the 10ScNCr/23 cell line (Lorenz et al. 2002).

Exotoxins

The enterotoxin of *B. fragilis* is a protease specific for E-cadherin and it promotes the reorganization of the actin cytoskeleton (Richard et al. 1999). Similarly, protease-active protein from *P. gingivalis* induces N-cadherin proteolysis, loss of cell adhesion, and apoptosis in human epithelial cells (Chen et al. 2001). Bacterial toxins that modify the actin cytoskeleton induce various cell dysfunctions including changes in the cell barrier permeability and disruption of intercellular junctions.

Enterotoxigenic *B. fragilis* (ETBF) are present in children and adults. They are distinguished by secretion of a 20 kDa zinc metalloprotease toxin (*B. fragilis* toxin (BFT)) (Sears 2001). Three isotypes of BFT are encoded by distinct *bft* loci which are located in a 6-kb chromosomal region unique to ETBF strains termed *B. fragilis* pathogenicity island (BfPAI). The pathogenicity island and its flanking regions (approximately 700 bp upstream of the *bft* gene) are important to optimal BFT activity (Franco et al. 2002). Interestingly, the BfPAI and its flanking region may be two distinct genetic elements (Franco et al. 1999). Attempts to construct a three-dimensional model of BFT 2 were recently undertaken in our laboratory (Schmid et al. 2004, unpublished) using protein sequence data, crystalline metalloproteinase structures, and Silicon Graphics software (Figure 4).

Adhesion

Bacterial fimbriae play an important role in the interaction between bacteria and host cells or among bacterial cells. *P. gingivalis* fimbriae have been studied most extensively. Its fimbrial structure is composed of 41-kDA fimbrillin proteins. The structure of the fimbrillin gene (*fimA*) shows intraspecies variation, but the common immunological specificities are retained (Hamada et al. 1998). *P. gingivalis* fimbriae have a variety of biological activities, including immunogenicity, binding to various host proteins, stimulation of cytokine production, and promotion of bone resorption. The fimbriae of *P. intermedia* induce hemagglutination reaction, while those of *P. loescheii* cause coaggregation with other bacteria. Also N-acetylneuraminic acid and glucuronic acid are involved in the attachment of *P. gingivalis* to epithelial cells (Agnani et al. 2003).

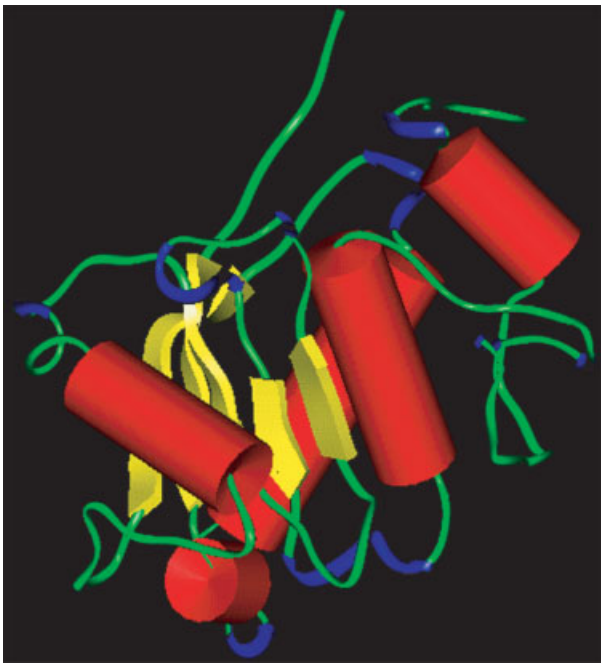

Figure 4 *The deduced three-dimensional crystal structure of the metalloproteinase encoded by* bft. *The α-helices are shown in red, while the β-sheets are in yellow with the arrow tip displaying the direction. The blue strands indicate the turns, while the green strands depict the amino acid residues which, according to computer predictions, do not fold into secondary structures.*

Invasion

Invasion of epithelial cells may be an important virulence factor in bacteria. Dorn et al. (1998) reported that *P. intermedia* can invade an oral epithelial cell line and that the type C fimbriae and a cytoskeletal rearrangement are required for invasion. Entry rates of *P. gingivalis* into gingival epithelial cells are high and rapid and internalized bacteria congregate in the perinuclear region of the cells (Belton et al. 1999). *P. gingivalis* remained inside the epithelial cells for over a 24-h period and induced rearrangement of the actin cytoskeleton along with alteration of the size and shape of the

epithelial cells. In coronary artery endothelial cells, *P. gingivalis* evades the endocytic pathway to lysosomes and instead traffics to the autophagosome (Dorn et al. 2002a, b). Microorganisms associated with root canal infections can invade primary cultures of cardiovascular cells (Dorn et al. 2002c). Further, periodontal pathogens such as *P. gingivalis*, *P. intermedia*, *Actinobacillus actinomycetemcomitans*, and *B. forsythus* are present in atherosclerotic plaque where they may play a role in development and progression of atherosclerosis possibly ending with coronary valvular disease and other clinical sequelae (Mastragelopulos et al. 2002). Long-term systemic challenge with *P. gingivalis* can accelerate atherogenic plaque progression as shown in a heterozygous apolipoprotein E-deficient murine model (Li et al. 2002). *P. gingivalis* also seems to cause lymphocyte apoptosis in peripheral blood mononuclear cells and this may be an important feature of this pathogen in periodontal disease (Geatch et al. 1999).

Abscess formation

B. fragilis is the anaerobe most frequently isolated from intraabdominal abscesses. The abscessogenic nature of *B. fragilis* is related to capsular polysaccharide, a polysaccharide biosynthesis locus being required for virulence (Coyne et al. 2001). Two capsular polysaccharides from *B. fragilis*, PS A1 and PS A1 from strain 9343, have been characterized structurally. Their most striking feature is a zwitterionic charge motif consisting of both positively and negatively charged substituent groups on each repeating unit (Kalka-Moll et al. 2001). The zwitterionic motif is essential in abscess formation.

Neutrophil and monocyte responses

In periodontitis, polymorphonuclear neutrophils (PMNL), primed or stimulated by the presence or persistence of infection, express an elevated and excessive response (Kantarci and Van Dyke 2002). This in turn leads to tissue destruction mediated by neutrophil activity.

The reduced susceptibility to phagocytosis found among some periodontopathogenic anaerobes may account for the differences between invasive and noninvasive stains. Thus a great diversity in phagocytosis susceptibility was determined by estimating the portion of phagocytosing PMNL ranging from 10.6 percent (strain W83) to >99.4 percent (ATCC 33277^T) in *P. gingivalis* and from 15.9 percent (strain MH5) to >95 percent (ATCC 33563^T) in *P. nigrescens* (Conrads et al. 1999). Eick et al. (2000) found that the PMNL of patients with rapidly progressive periodontitis show deficiencies in phagocytic activity and in intracellular killing of periodontopathogenic bacteria.

Proteases/protease inhibitors

P. gingivalis in a nonfermentative species requiring peptides for growth which in vivo are probably derived from the hydrolysis of native proteins by an extracellular proteinase (Shah and Williams 1987a). The enzyme appears to be a major virulence determinant and was fully characterized as a cysteine proteinase and designated the name, gingivain (Shah et al. 1991). This was subsequently confirmed by several workers who then referred to the same enzyme as gingipain.

This enzyme subverts host defense systems with the complement and neutrophils being the main targets (Potempa et al. 2000). They also contribute to local generation of bradykinin and thrombin through uncontrolled activation of the kallikrein/kinin pathway and the coagulation cascade. Bradykinin and thrombin are synergistically working proinflammatory reagents with a strong stimulatory effect on bone resorption. Lourbakos et al. (2001) found that arginine-specific gingipains-R (RgpB and HRgpA) induced an increase in intracellular calcium in human platelets at nanomolar concentrations and caused platelet aggregation with efficiency comparable to thrombin. HRgp may be more important in the virulence of *P. gingivalis* relative to rgpB because of the presence of the hemagglutinin/adhesion domain which can bind phospholipids and modulate enzyme activity (Imamura et al. 2000). Furthermore, gingipains have a strong effect on mechanisms controling host matrix metalloproteinase at the level of gene expression and zymogen activation (Potempa et al. 2000). The action of gingipains and other proteinases produced locally by subgingival bacteria would dysregulate most mechanisms controlling inflammatory reaction.

The genera *Fusobacterium* and *Leptotrichia* include several species of nonsporing and nonmotile gram-negative, pleomorphic rods. They have in common a low guanine plus cytosine (G+C) ratio and there are distinct similarities in whole-cell fatty-acid patterns. *Fusobacterium* spp. are obligately anaerobic, whereas most *Leptotrichia* strains are aerotolerant. In contrast to *Fusobacterium*, all species of which are virtually asaccharolytic, *Leptotrichia* ferments glucose and a range of other carbohydrates. The habitat of both is the mucous membranes of man and animals.

Fusobacterium and *Leptotrichia* are phylogenetically related. Both genera are evolutionarily closer to the gram-positive than the gram-negative bacteria. In the phylogenetic classification of Woese (Woese 1987) *Fusobacterium* and *Leptotrichia* are assigned to a separate division within the Bacteria (Neefs et al. 1993; Olsen et al. 1994).

FUSOBACTERIUM

DEFINITION OF THE GENUS

Fusobacterium spp. are gram-negative rods that are nonsporing, nonmotile, and obligately anaerobic. The cells are often pleomorphic, may be filamentous, and are spindle-shaped with pointed ends ('fusiform') in a few species. Amino acids and peptides are used for energy metabolism. *n*-Butyric acid is a major metabolic product. Threonine is deaminated to propionic acid. The G + C content of DNA is 26–34 mol% and the type species of the genus is *Fusobacterium nucleatum*.

HISTORICAL PERSPECTIVE

The generic name *Fusobacterium* was introduced by Knorr (1923) for obligately gram-negative bacilli that were fusiform. He described three species: *Fusobacterium plauti-vincenti*, *Fusobacterium nucleatum*, and *Fusobacterium polymorphum*. The species name *F. plauti-vincenti* was given to the spindle-shaped organism observed in materials recovered from ulcerative stomatitis by Plaut (1894) and Vincent (1896) and cultivated and named *Bacillus fusiformis* by Veillon and Zuber (1898). This organism is now assigned to the genus *Leptotrichia* under the name *Leptotrichia buccalis*.

Loeffler, in 1884, observed pleomorphic rods in diphtheroid lesions of calves and doves. The organism,

named *Bacillus necrophorus* by Flügge (1886), was cultured by Bang (1890–91) from necrotic lesions of a number of domestic animals and by Schmorl (1891) from an epizootic in rabbits. Prévot (1938) proposed the term *Sphaerophorus* for the pleomorphic anaerobic gram-negative rods that were not fusiform. The seventh edition of the *Bergey's manual* divided the family Bacteroidaceae into three genera: *Bacteroides*, defined as rods with rounded ends; *Fusobacterium*, defined as rods with tapering ends; and *Sphaerophorus*, defined as rods with rounded ends that showed a marked pleomorphism and in which filaments were common. Studies of DNA base ratios (Sebald 1962) and physiological studies performed in the 1960s and the early 1970s indicated that there was no valid basis for separating the genera *Fusobacterium* and *Sphaerophorus*. In the eighth edition of the *Bergey's manual* the valid species included in *Sphaerophorus* were transformed to the genus *Fusobacterium*.

Bergey's manual of systematic bacteriology lists ten *Fusobacterium* species: *F. nucleatum*, *F. gonidiaformans*, *F. varium*, *F. necrophorum*, *F. perfoetens*, *F. naviforme*, *F. russii*, *F. mortiferum*, *F. necrogenes*, and *F. prausnitzii*. Four new species were described subsequently: *F. simiae* (Slots and Potts 1982), *F. periodonticum* (Slots et al. 1983). *F. ulcerans* (Adriaans and Shah 1988), and *F. equinum* (Dorsch et al. 2001). The taxonomic position of *F. perfoetens* is in doubt. The proposed neotype strain (ATCC 29250) (van Assche and Wilssens 1977) is an ovoid coccobacillus distantly related to the other *Fusobacterium* spp. (Conrads et al. 2002). *F. prausnitzii*, which has a DNA G + C composition of 52–57 mol%, is phylogenetically very distant from the genus *Fusobacterium* (Wang et al. 1996; Conrads et al. 2002). *F. alocis* and *F. sulci*, described as new species from the human gingival sulcus (Cato et al. 1985), have been reclassified as *Filifactor alocis* and *Eubacterium sulci*, respectively (Jalava and Eerola 1999).

CLASSIFICATION

The genus *Fusobacterium* is phenotypically relatively homogeneous. Comparison of small-subunit rRNA sequences has revealed levels of sequence similarity that are consistent with a single genus, but intrageneric heterogeneity is evident (Lawson et al. 1991; Tanner et al. 1994). *F. nucleatum*, the species isolated most frequently from man, is divided into five subspecies: *F. nucleatum* subsp. *nucleatum*, subsp. *polymorphum*, subsp. *vincentii*, subsp. *fusiforme*, and subsp. *animalis*, described on the basis of electrophoretic patterns of whole-cell proteins and DNA homology (Dzink et al. 1990) and electrophoretic mobility of two enzymes and DNA homology (Gharbia and Shah 1992). The five subspecies of *F. nucleatum* differed from each other and from the other closely related species by comparison of their 16S–23S internal transcribed spacer regions (Conrads et al. 2002), which supported the validity of previous descriptions. Another potential new subspecies has been isolated from dog- and cat-bite wounds. It is intrinsically quinolone-resistant (Goldstein et al. 2002) and phylogenetically distinct from the five other subspecies. The name '*Fusobacterium canifelium*' has been proposed (Citron 2002). *F. periodonticum* falls phylogenetically within *F. nucleatum* (Jousimies-Somer and Summanen 2002). Animal isolates of *F. necrophorum* fall within two subspecies: *F. necrophorum* subsp. *necrophorum* and *F. necrophorum* subsp. *funduliforme* (Shinjo et al. 1991), corresponding to biovars A and B. While *F. necrophorum* subsp. *necrophorum* contains the isoleucine and alanine tRNA gene, *F. necrophorum* subsp. *funduliforme* contains the isoleucine tRNA gene (Jin et al. 2002). Southern blot hybridization analysis detected different patterns of leukotoxin A (lktA) hybridizing bands between isolates of the two subspecies of *F. necrophorum* (Narayanan et al. 2001a).

F. mortiferum, *F. varium*, and *F. ulcerans* share several phenotypic properties similar to *F. varium*, but *F. ulcerans* reduces nitrate to nitrite (Citron 2002). It also contains unique fragments of 1000 and 550 bp not present in *F. varium* and *F. mortiferum* (Claros et al. 1999). *F. necrogenes* is distantly related to the other *Fusobacterium* spp. as seen from 16S–23S rDNA spacer region sequences (Citron 2002). *F. gonidiaformans* is genealogically related to *F. necrophorum* (Nicholson et al. 1994).

HABITAT

The fusobacteria are normal inhabitants of the mucous membranes of man and animals. The habitat of *F. nucleatum* and *F. periodonticum* is the human oral cavity; the gingival crevice is the niche of both. *F. nucleatum* is a constant member of the oral microflora of adults and children and is also found in edentulous infants. The relatively frequent isolation of *F. necrophorum* from soft-tissue infections of the oral cavity and the upper respiratory tract, compared with anaerobic infections elsewhere in the body, indicates these regions to be the principal human habitat of this organism. The vagina is likely the primary endogenous site for *F. naviforme* and *F. gonidiaformans* (Hill 1993). The habitat of *F. mortiferum* and *F. varium* is the gastroenteral tract, where they are present in small numbers. *F. necrogenes*, which was originally isolated from a chicken abscess and from cecal contents of ducks, is very rarely isolated from man. The habitat of *F. ulcerans*, isolated from tropical ulcers, is unknown.

F. necrophorum is a normal inhabitant of the alimentary tract of cattle, horses, sheep, and pigs and is frequently isolated from cats and dogs. Reports, mainly from the first part of the twentieth century, indicate its presence in a range of wild animals, including reptiles.

F. russii is normally found in the canine and feline oral flora (Love et al. 1987), but it has also been isolated from human feces. The oral cavity is the likely habitat of *F. equinum* and *F. simiae*, isolated from horse and the stump-tailed macaque (*Macaca arctoides*), respectively. Intragroup DNA homology studies of isolates and of human- and animal-type strains have indicated that similar sites in man and animals may have their own genetic clusters of phenotypically similar fusobacteria (Love et al. 1987).

MORPHOLOGY

Fusobacteria are aflagellar gram-negative rods of varied morphology. The bacterial cells range from short to very long and filamentous; some strains are coccobacilli. Width is variable. The cells may be single, be in pairs end to end, or form long, coiled filaments. Staining may be irregular and spheroplasts are common in some species.

The cells of *F. nucleatum* are slender, spindle-shaped bacilli with tapered or pointed ends, 0.4–0.7 μm thick and 4–10 μm long, appearing singly, in tandem pairs, or in bundles or sheaves of roughly parallel bacilli. Cell length is usually uniform among actively growing cells. The cells may have a beaded appearance due to the presence of intracellular granules. Filaments may be seen in old cultures. *F. periodonticum* and *F. simiae* have a similar cellular morphology. The cells of *F. necrophorum* are pleomorphic, often curved, with rounded and sometimes tapered ends, and they may have spherical enlargements. Free coccoid bodies and, especially, filaments are common. Cell length may vary from coccobacilli to long threads in material from human infections. The organism is a more regular bacillus in young cultures. Except in young cultures, staining is irregular and beaded forms are common. *F. naviforme* strains may have boat-shaped cells. Gonidial forms may be seen in old cultures of *F. gonidiaformans*. *F. varium* is a small bacillus that does not form filaments or spheroplasts. Strains of *F. mortiferum* may be extremely pleomorphic with globular forms, swellings, and threads. Short rods are predominant in cultures of *F. equinum*. The other fusobacteria are pleomorphic filamentous organisms.

CULTURAL CHARACTERISTICS

Fusobacteria are not particularly demanding with regard to a low oxidation–reduction potential. They are, however, killed fairly readily by exposure to oxygen. This is possibly due to their susceptibility to peroxides. Growth is best at 35–37°C and at a pH near 7.

All *Fusobacterium* spp. grow more or less readily on blood agar based on proteose–peptone, tryptone, or trypticase. Good growth is usually obtained in a rich semifluid medium such as brain–heart medium supplemented with yeast extract. Batch cultivation is best performed in a fluid medium containing a reducing agent. If narrow-necked, well-filled containers are used, pre-reduced, anaerobically sterilized (PRAS) media are usually not necessary.

Surface colonies of *F. nucleatum* are 1–2 mm in diameter after incubation for 2 days. They are white to yellow-gray in color, speckled, smooth, or breadcrumb-like. The colonies are usually nonhemolytic. Cultures of *F. nucleatum* produce an unpleasant, but not fetid, smell.

After incubation for 2 days, colonies of animal isolates of *F. necrophorum* are about 2 mm in diameter, flat, circular with scalloped to erase edge, opaque, and white to gray (subsp. *necrophorum*); or 1 mm wide, circular with entire margins, gray, translucent and with smooth surfaces (subsp. *funduliforme*) (Shinjo et al. 1991). *F. necrophorum* subsp. *necrophorum* is strongly β-hemolytic; β-hemolysis is usually weaker in subsp. *funduliforme* and may need incubation for 3 or more days to develop. Cultures of *F. necrophorum* produce a foul, putrid odor. Fluid or semifluid cultures are characterized by abundant production of gas.

The colonial morphology of *F. necrophorum* isolated from human infections is similar to that of *F. necrophorum* subsp. *funduliforme*. The colonies are small and have been described as creamy, opaque, smooth, umbonate or raised, and with entire edges (Hall et al. 1997). The colonial morphology of most other *Fusobacterium* spp. is similar to that of *F. necrophorum* subsp. *funduliforme*.

GENETICS

The genome of *F. nucleatum* (strain ATCC 25586^T) contains 2.17 Mb encoding 2067 open reading frames (ORF) organized on a single circular chromosome with a G + C content of 27 percent (Kapatral et al. 2002). About 3.5 percent of the ORFs are unique to *F. nucleatum*. There are fewer chromosomal clusters between *F. nucleatum* and *Escherichia coli* than between *F. nucleatum* and gram-positive bacteria such as *Clostridium* spp. and *Bacillus subtilis*. This corroborates the allocation, based on 16S rRNA sequences, of *F. nucleatum* in the low-G + C gram-positive bacterial group.

F. nucleatum strain ATCC 25586^T did not contain any plasmids. However, plasmids have been found in other *F. nucleatum* strains (McKay et al. 1995; Haake et al. 2000). Bacteriocin production has been reported in *F. nucleatum* and *F. mortiferum* (Oliveira et al. 1998; Portrait et al. 2000).

Different methods for genotyping, i.e. allozyme electrophoresis, ribotyping, the arbitrarily primed polymerase chain reaction (PCR), and examination of ribosomal RNA gene restriction patterns, have been used for studying heterogeneity (Lawson et al. 1991; George et al. 1997; Morris et al. 1997; Thurnheer et al. 1999), identification and epidemiologic subtyping (Avila-

Campos et al. 1999), and intrafamiliar transmission of oral *F. nucleatum* isolates (Suchett-Kaye et al. 1999). Ribotyping has also been used to demonstrate similarity between *F. necrophorum* isolates from bovine liver abscesses and ruminal contents (Narayanan et al. 1997).

METABOLISM

The core metabolism of *F. nucleatum* is similar to that of *Clostridium*-, *Lactococcus*-, and *Enterococcus* species (Kapatral et al. 2002). More than 137 transporters for the uptake of substrates such as peptides, sugars, metal ions, and cofactors have been detected. Amino acids and small peptides comprise the major sources of energy for all *Fusobacterium* spp., but sugars may be used when amino acids are not available. Acidic and cationic amino acids are the main acids incorporated. Glutamate, histidine, lysine, and serine appear to be key amino acids in *F. nucleatum* (Dzink and Socransky 1990; Rogers et al. 1992). Remaining amino acids are imported as such or as di- or oligopeptides, which are degraded in the bacterial cytoplasm. An active transport of the dipeptide L-cysteinglycine has been detected in *F. nucleatum* (Carlsson et al. 1994). Small peptides may also be cleaved outside the bacterial cell (Bakken et al. 1989b).

Biosynthetic pathways exist for only glutamate, aspartate, and asparigine (Kapatral et al. 2002), and aspartylaspartate and glutamylglutamate can be used as growth substrates for *F. nucleatum* (Takahashi and Sato 2002). Glutamate is a key catabolic substrate in *Fusobacterium* spp. It is catabolized via the 2-oxoglutarate pathway with the production of acetate and butyrate as end products (Gharbia and Shah 1991). Glutamate may also be degraded by the methylaspartate pathway in *F. varium* (Gharbia and Shah 1991). Enzymes representative for the mesaconate pathway for catabolism of glutamate have been detected in *F. varium*, *F. mortiferum*, and *F. ulcerans* (Gharbia and Shah 1991). *F. varium* and *F. mortiferum* also possess enzymes representative of the 4-aminobutyrate pathway. The 3-keto-aminohexamate pathway catabolizes lysine (Barker et al. 1982).

Fusobacterium spp. differ in their ability to use fermentable carbohydrate as energy source for growth (Robrish et al. 1991). *F. nucleatum* and other species utilize glucose for biosynthesis of intracellular glycopolymers that can be degraded to produce energy under conditions of amino-acid deprivation (Robrish and Thompson 1988). The accumulation of glucose is dependent on energy generated by the fermentation of amino acids (Robrish et al. 1987). *F. mortiferum* is an exception in that accumulation of sugars is independent of a fermentable amino acid. Significantly, *F. mortiferum* has the ability to metabolize various sugars as energy sources for growth (Robrish et al. 1991). The range of sugars includes, among others, α- and β-glycosides, which are transported by the phosphoenolpyruvate (PEP)-dependent sugar: phosphotransferase system (PTS). Thus, it utilizes sucrose [glucose-fructose in α(1→2) linkage] and its five isomeric α-D-glucosyl-D-fructoses as energy sources for growth (Pikis et al. 2002). Phospho-β-glucosidase (P-β-glucosidase; EC 3.22.1.86) and 6-phospho-α-D-glucosidase (maltose-6-phosphate hydrolase; EC 3.2.1.122) from *F. mortiferum* have been purified and the encoding genes, *pbgA* and *malH*, respectively, have been expressed in *E. coli* (Bouma et al. 1997; Thompson et al. 1997).

All fusobacteria, except *F. naviforme* and *F. russii*, produce propionate from threonine. Lactate is converted to propionate by *F. necrophorum* and *F. varium*. Fusobacteria form volatile sulfur compounds from cysteine and methionine (Pianotti et al. 1986; Claesson et al. 1990).

CELL-WALL COMPOSITION; ANTIGENIC STRUCTURE

The fusobacteria have a cell-wall structure typical of gram-negative bacteria: an inner (cytoplasmic) and outer membrane, separated by a periplasmic space containing the peptidoglycan layer.

meso-Lanthionine, the monosulfur analog to *meso*-diaminopimelic acid, replaces the latter as the diamino acid present in the peptidoglycan of *F. nucleatum*, *F. gonidiaformans*, *F. necrophorum*, *F. russii*, *F. necrogenes*, *F. simiae*, and *F. periodonticum* (Kato et al. 1981; Vasstrand et al. 1982; Gharbia and Shah 1990). *meso*-Lanthionine is synthesized as such and then incorporated into the peptidoglycan pentapeptide (Fredriksen et al. 1991). *meso*-Diaminopimelic acid is present in the peptidoglycan of *F. varium*, *F. naviforme*, and *F. ulcerans*. The peptidoglycan layer of *F. mortiferum* contains both diamino acids.

The outer membrane is an asymmetric, multilayered membrane consisting of phospholipid, lipoprotein, lipopolysaccharide (LPS), and protein. Fusobacterial LPS shares the general LPS architecture of a heteropolysaccharide, exhibiting O-antigenic specificity, linked to lipid A through 2-keto-3-deoxyoctonate. The lipid A of *F. nucleatum* exhibits close structural relationship to that of enterobacterial LPS and cross-reacts serologically with antibodies to *E. coli* lipid A (Dahlén and Mattsby-Baltzer 1983). *F. necrophorum* subsp. *funduliforme* and human *F. necrophorum* isolates have a rough-type LPS, whereas that of *F. necrophorum* subsp. *necrophorum* is of the smooth type (Brown et al. 1997). The repeat unit of the O-antigenic polysaccharide of *F. necrophorum* LPS is an acid identified as a 2-amino-2-deoxy-2-C-methyl-pentonic acid (2-amino-2-methyl- 3,4,5-trihydroxypentanoic acid), a novel structure not found before in nature (Hermansson et al. 1993).

The dominating protein of the outer membrane of *F. nucleatum*, designated FomA, has a molecular mass of 40 kDa (Bakken et al. 1989a). It is a nonspecific porin

present in the outer membrane as a trimer (Kleivdal et al. 1995). The gene encoding the FomA porin has been sequenced (Bolstad and Jensen 1993a) and a topology model has been made (Bolstad et al. 1994). The deduced topology is similar to that of porin structures from other bacteria. The *fomA* gene has been cloned and expressed in *E. coli* (Jensen et al. 1996; Haake and Wang 1997). Several other outer-membrane proteins have been predicted from the genome sequence, among them some very-high-molecular-weight proteins (Kapatral et al. 2002). FomA and outer-membrane proteins with molecular masses of 55, 60, and 70 kDa seem to be major protein antigens in *F. nucleatum* (Bakken et al. 1989c). Heat-shock proteins (HSP) reacting with anti-*Yersinia enterocolitica* HSP60 and mycobacterial 65 kDa HSP have been detected in *F. nucleatum* (Ando et al. 1995). A homology between *F. nucleatum*, *Mycobacterium leprae*, and *E. coli* HSPs has been indicated (Skar and Bakken 2001).

The cellular fatty acids in the *Fusobacterium* spp. examined are straight-chain saturated and monoenoic acids of chain lengths C_{12}–C_{18} and O-3-hydroxytetradecanoate (Jantzen and Hofstad 1981). O-3-Hydroxyhexadecanoate is distinctive of the oral species *F. nucleatum*, *F. simiae*, and *F. periodonticum* (Jantzen and Hofstad 1981).

Unquestionable fimbriation or capsule formation has not been demonstrated in fusobacteria.

SUSCEPTIBILITY TO ANTIBACTERIAL AGENTS

A varying amount of *F. nucleatum* isolates produce β-lactamase, an activity not reported for other *Fusobacterium* species. A penicillin-hydrolyzing β-lactamase inhibited by clavulanic acid has been isolated from *F. nucleatum* (Tunér et al. 1985). *Fusobacterium* species are fully susceptible to amoxycillin/clavulanate, carbapenems, chloramphenicol, the new quinolone clinafloxalin, linezolide (Goldstein et al. 1999), and nitroimidazoles. Resistance to cefoxitin and clindamycin is very low. Resistance to tetracyclines in *F. nucleatum*, which is common, is due to the presence of the *tetM* gene located on the chromosome. A substantial number of *F. nucleatum* strains harbor the *tetM* determinant on a conjugal transposon (Roberts and Lansciardi 1990). Resistance to glycylglycines has not been observed (Downes et al. 1999). *F. nucleatum* is sensitive to the bactericidal action of protegrins and other antibacterial peptides (Miyasaki et al. 1998).

LABORATORY ISOLATION AND IDENTIFICATION

The isolation of fusobacteria from an anaerobic infection requires proper collection of the specimen, the use of an anaerobic transport vial, optimal anaerobiosis (an anaerobic chamber is not necessary), and a rich medium supplying optimal growth. Fastidious Anaerobe Agar Base (FAA, Lab M) supplemented with 5 percent sheep or horse blood is recommended for culture.

The use of a selective medium is necessary for the enumeration of viable fusobacteria in specimens of normal flora. The addition of josamycin, vancomycin, and norfloxacin plus 5 percent defibrinated horse blood to FAA promotes luxuriant growth of *Fusobacterium* spp. while completely inhibiting most other obligate anaerobes and facultative bacteria (Brazier et al. 1991). Rifampicin blood agar (Sutter et al. 1971) is useful for the selective isolation of *F. varium* and *F. mortiferum*.

All *Fusobacterium* spp. produce butyric acid but no isoacids. They are catalase- and nitrate-negative, sensitive to kanamycin (1000 μg disk) and colistin (10 μg disk), resistant to vancomycin (5 μg disk), and produce a rancid odor. A yellow fluorescence under longwave ultraviolet (UV) light is a common property of fusobacteria grown on blood agar based on FAA.

The characteristic cellular morphology of *F. nucleatum* makes a presumptive identification relatively easy. The fusiform cells of *L. buccalis* are thicker and usually larger (see Table 1) and those of *Capnocytophaga*

Table 1 *Characters differentiating* L. buccalis, F. nucleatum, *and* Capnocytophaga *spp.*

Character	*L. buccalis*	*F. nucleatum*	*Capnocytophaga*
Microscopic morphology (blood agar)	Gram-negative,[a] 5–15 μm long, thick fusiform bacilli	Gram-negative, 3–10 μm long, slender fusiform bacilli	Gram-negative, 3–6 μm long, slender fusiform bacilli
Colonial morphology	Smooth, rhizoid, or convoluted	Smooth, convex, 'flecked' appearance	Flat, rough, spreading margin,[b] adherent; or low-convex, smooth; yellow-pigmented
Growth in air + 5–10% CO_2	+	–	+
Acid from glucose	+	–	+
Production of indole	–	+	–
Main fatty acids from glucose/peptone	Lactic	Butyric	Acetic, succinic

a) Often gram-positive in young cultures.
b) Gliding motility.

spp. generally smaller. Moreover, *L. buccalis* and *Capnocytophaga* spp. are not obligate anaerobes.

The tests shown in Table 2 are useful for the identification of species within the genus *Fusobacterium*. The properties listed for *F. nucleatum* and *F. russii* are shared with *F. periodonticum*. Diagnostic tablets are convenient for the examination of bile resistance, production of alkaline phosphatase, and orthonitrophenol-beta-D-galactopyranoside (ONPG)-test. Commercially available kits based on the detection of preformed enzymes and designed for identification of anaerobes may be of help in supporting a suspected identity of a *Fusobacterium* isolate. The Rapid ID 32A system (bioMérieux), which provides a rapid and reliable method for identification of non-*B. fragilis* group anaerobic gram-negative bacilli to the genus level, discriminates poorly between *F. nucleatum* and *F. necrophorum* (Downes et al. 1999). *Fusobacterium* species differ in their ability to hydrolyze endopeptidase and amino- and diamino peptidase substrates (Beighton et al. 1997).

Determination of the electrophoretic migration of glutamate dehydrogenase and 2-oxoglutarate reductase provides a rapid method for the identification of most *Fusobacterium* spp. (Gharbia and Shah 1990). Identification based on gas–liquid chromatography of cellular fatty acids may be of value in reference laboratories, provided a database is used as a basis for comparison. Of greater potential in the diagnostic laboratory is the use of nucleic-acid probes. A genomic DNA probe has been used successfully to detect *F. nucleatum* directly in samples of subgingival plaque (Lippke et al. 1991) and checkerboard DNA–DNA hybridization has been used to detect *F. nucleatum* and subspecies in periodontal and endodontic infections (Socransky et al. 1998; Sunde et al. 2000). A PCR-amplified nonradioactive probe coding for part of the major 40-kDa outer-membrane protein, the FomA porin, of *F. nucleatum* and seemingly specific for the species when used under condition of high stringency, has been constructed (Bolstad and Jensen 1993b). So far, automated DNA sequencing for identification of particular *Fusobacterium* isolates is best suited for the reference laboratory.

ROLE IN NORMAL FLORA

Coaggregation, adherence of cells of different species or strains among resident bacteria, is an important event in the formation of biofilms such as dental plaque (Kolenbrander and London 1993). *F. nucleatum* is one of the bacterial species most frequently isolated in plaque from healthy sites. The organism coaggregates with several other oral bacterial species and is proposed to act as a bridge between bacteria that adhere early to the tooth surface and the late colonizers (Bolstad et al. 1996). It may be a key organism in the development, maintenance, and stabilization of the microbial flora of the gingival crevice. *F. nucleatum* and *F. periodonticum* coaggregate with *Candida albicans* (Grimaudo and Nesbitt 1997). Coaggregation is a specific process dependent on surface-associated adherence proteins. The nature of the fusobacterial adherence proteins is largely unknown. Galactose and *N*-acetylneuraminic acid-binding adhesins have been identified (Shaniztki et al. 1997, 1998).

The role played by fusobacteria in other ecosystems where fusobacteria are present in low numbers is virtually unknown.

PATHOGENICITY AND VIRULENCE FACTORS

Pathogenic fusobacteria are in particular isolated from inflammatory processes accompanied by necrosis and ulceration. *F. nucleatum* constitutes about two-thirds of the *Fusobacterium* isolates. Next to the most prevalent

a) Rarely isolated from clinical specimens.

b) Isolated from topical ulcers only.

Bacteroides and *Prevotella* species, *F. nucleatum* is the gram-negative anaerobic organism most often encountered in human infections. It is most frequently isolated from infections of the mouth, head, and neck, pleuropulmonary infections, and abscesses of the brain and liver. *F. nucleatum* is one of several bacterial species associated with periodontitis in adults. It causes desulfuration of cysteine and methionine, yielding ammonia, H_2S, methyl mercaptan, and butyrate, which are capable of arresting fibroblast growth and thereby preventing wound healing and aiding penetration of the gingival epithelium (Kapatral et al. 2002). *F. nucleatum* has been exclusively recovered from the amniotic fluid of women with preterm delivery (Holst et al. 1994).

F. necrophorum is the cause of necrobacillosis in man and animals. Lemierre's syndrome is the classical presentation of human necrobacillosis (Lemierre 1936; Kristensen and Prag 2000).This is a specifically recognizable, rare, but serious disease starting with acute sore throat with purulent exudate in a previously healthy young adult who subsequently develops septicemia with disseminated metastatic abscesses, frequently including a septic thrombophlebitis of the jugular vein. *F. necrophorum* is frequently found in specimens from peritonsillar abscesses. The organism is isolated more seldom from purulent infections elsewhere in the body. Human *F. necrophorum* isolates resemble animal strains of *F. necrophorum* subsp. *funduliforme* (Hall et al. 1997). In contrast, necrobacillosis in animals is caused by *F. necrophorum* subsp. *necrophorum*, which is an important animal pathogen that is frequently isolated from necrotic and gangrenous lesions in domestic and wild animals. The most common manifestations associated with the organism are liver abscesses and foot rot in cattle and sheep. *F. necrophorum* subsp. *funduliforme* is a weak pathogen in animals. Human and animal clinical *F. necrophorum* isolates are thus distinct, as are the diseases caused.

The other *Fusobacterium* spp. are occasionally isolated from human infections. *F. russii* may be found in infected dog and cat bites.

Current knowledge of bacterial products or strategies that enable pathogenic fusobacteria to colonize and invade, and to damage the host, is sparse. The role played by the lipopolysaccharide and other cell-wall components in the pathogenesis of anaerobic infections involving fusobacteria has not been resolved. Fc-binding activity in *F. nucleatum* has been associated with polypeptides of 40 and 42 kDa (Guo et al. 2000).

The genome of *F. nucleatum* contains several ORFs that code for putative virulence factors, among them three hemolysins (Kapatral et al. 2002). The organism agglutinates human erythrocytes and attaches to human oral epithelial cells, gingival fibroblasts, and polymorphonuclear leukocytes (Bolstad et al. 1996). *F. nucleatum* also binds to collagen (Xie et al. 1991), fibronectin (Isogai et al. 1992), and a glycosylated protein-rich glycoprotein in the parotid saliva (Gillece-Castro et al. 1991). An immunosuppressive protein, FiP, that arrests human T cells in the mid-G_1 phase of the cell cycle, has been isolated (Shenker and Datar 1995). The encoding gene, *fipA*, has been characterized, cloned, and expressed in *E. coli* (Demuth et al. 1996). It seems that the *fipA* gene is highly conserved among *F. nucleatum* strains and that *fipA* homologs are widely distributed among fusobacteria (Gerardo et al. 2002). Induction of apoptotic cell death in human leukocytes by *F. nucleatum* has been reported (Jewett et al. 2000).

F. necrophorum produces a leukotoxic protein with specificity for ruminant leukocytes (Emery et al. 1984). The toxin has been cloned and sequenced (Narayanan et al. 2001b). It induces activation and apoptosis of bovine leukocytes (Narayanan et al. 2002). Large amounts are produced by *F. necrophorum* subsp. *necrophorum*. The *F. necrophorum* hemolysin is a phospholipase distinct from the leukotoxin (Fifis et al. 1996). A cell-wall preparation from *F. necrophorum* subsp. *necrophorum* has been shown to be collagenolytic (Okamoto et al. 2001).

LEPTOTRICHIA

DEFINITION

Leptotrichia species are gram-negative, large fusiform rods that are nonsporing and nonmotile. They are usually anaerobic on first isolation; most strains grow aerobically in the presence of CO_2. Carbohydrates are used for energy metabolism. Lactic acid is a major metabolic product. The type species of the genus is *L. buccalis* and the G + C content of DNA of the type strain ATCC 14201^T is 25 mol%.

HISTORICAL PERSPECTIVE

The generic name *Leptotrichia* was introduced by Trevisan (1879) for filamentous organisms found in the human mouth. Several years earlier Robin (1853) used the species designation *buccalis* for filamentous forms (*Leptothrix buccalis*) observed in wet mounts of tooth scrapings. *L. buccalis* was first cultured by Wherry and Oliver (1916) and carefully described by Thjøtta et al. (1939). In 1995, another species, *Leptotrichia sanguinegens* ('*Leptotrichia microbii*'), was proposed for a serum-requiring, anaerobic, gram-negative rod isolated from the blood of patients with postpartum and neonatal bacteremia (Hanff et al. 1995). Recently, this organism was transferred to the new genus *Sneathia* as *Sneathia sanguinegens* (Collins et al. 2001). *L. trevisanii* (Tee et al. 2001) and *L. amnionii* (Shukla et al. 2002) have been suggested as additional *Leptotrichia* species. The name *L. trevisanii* was validly published in 2002 (Validation list No. 85 2002), while the name *L. amnionii* has not

been validated so far. Four new *Leptotrichia* species, i.e. *L. goodfellowii*, *L. hofstadii*, *L. shahii*, and *L. wadei* have been established by Eribe et al. (2004).

In *Bergey's Manual of systematic bacteriology*, *Leptotrichia* is classified as the third genus in the family Bacteroidaceae. In the past *L. buccalis* has been confused with *Fusobacterium* spp. and, because of the frequent occurrence in young cultures of gram-positive stained cells, it has also been mistaken for gram-positive bacilli related to lactobacilli. The name *Leptotrichia* has been used for the gram-positive organism termed *L. dentium* by Davis and Baird-Parker (1959) and now classified as *Corynebacterium matruchotii* (Collins and Cummins 1986).

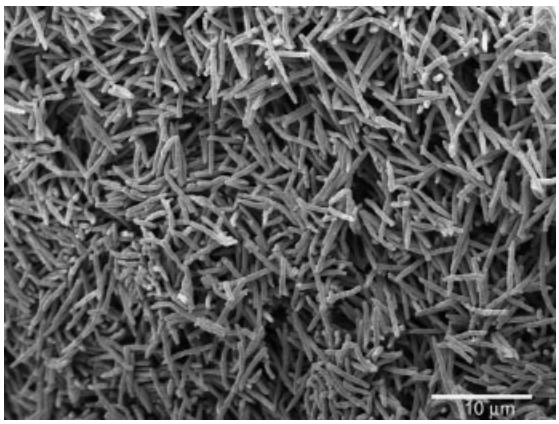

Figure 1 *Scanning electron microscopy of* L. buccalis *cells in a colony*

CLASSIFICATION

Isolates described in the literature as members of the species *L. buccalis* differ with respect to phenotypic characteristics, such as cellular and colonial morphology, aerotolerance, fermentation of sugars, cellular fatty-acid composition, and G + C content (Morgenstein et al. 1980; Duperval et al. 1984; Reig et al. 1985; Hofstad and Naess 1992; Eribe et al. 2002). This indicates heterogeneity of the species, which is being further demonstrated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of whole-cell proteins and random amplified polymorphic DNA (RAPD) (Eribe and Olsen 2002), and results of 16S rRNA-sequencing and DNA–DNA homology confirmed the presence of additional *Leptotrichia* species (Eribe et al. 2004).

HABITAT

The human habitat of *L. buccalis* is the oral cavity, where dental plaque is the principal niche. The organism is present in adults and children and has been found in the mouth of edentulous infants (Könönen et al. 1994), and seems to colonize permucosal implants of edentulous patients (Nakou et al. 1987). *L. buccalis* has also been isolated from the periurethral region of the vagina (Bollgren et al. 1979), from dog bites (Goldstein et al. 1978), and in infections of domestic animals (Hirsh et al. 1979). The role of *L. buccalis* in the normal microflora is unknown.

L. trevisanii was isolated from the blood of a man diagnosed as having acute myeloid leukemia (Tee et al. 2001).

MORPHOLOGY

L. buccalis is an aflagellar, straight or slightly curved rod, 0.8–1.5 µm wide and 5–15 µm long; one or both ends are pointed end or rounded. A very large gram-negative bacillus with one pointed end and one square end is particularly suggestive of *L. buccalis*. In gram-stained smears of 48 h cultures the organism appears as gram-negative cells often with gram-positive granules, singly or in pairs, end to end, and in a 'straw-like' arrangement (Figure 1). Young cultures show a varying proportion of gram-positive cells. Thread forms and chains may be present in smears made from old, filamentous colonies. An unusual ultramicroscopic feature is a ridged surface structure formed by an assay of macromolecules erected on the surface like a fence with closely set vertical pales (Listgarten and Lai 1975). 0.8–0.9 µm wide and 6–13 µm long, fusiform, nonmotile gram-negative cells, many of which are curved, with tapered ends characterizing *L. trevisanii*. (Tee et al. 2001). The cell ends are flattened where they join.

CULTURAL CHARACTERISTICS AND METABOLISM

L. buccalis grows well under anaerobic or microaerobic conditions, but poorly in air even in the presence of CO_2 (Hofstad and Næss 1992). Surface colonies on blood agar medium are 2–3 mm in diameter after incubation anaerobically for 2 days, smooth, colorless, sometimes raised, and with a filamentous edge (Figure 2), nonadherent, and nonhemolytic. After prolonged incubation the surface of the colonies becomes convoluted, resembling that of a human brain.

L. trevisanii grows both anaerobically and under 5 percent CO_2 (in air) on subsequent culture on solid media (Tee et al. 2001). On horse-blood agar plates the colonies are smooth, grayish in color, low convex, and with an erosed edge. They appear with a dark central spot with transillumination and grow to about 2 mm in diameter after 5 days of incubation. Older colonies show a slightly convoluted surface.

L. buccalis is highly saccharolytic. Mono- and disaccharides are fermented with the production of lactic acid alone, or accompanied by trace amounts of acetic and succinic acids. The terminal pH is 5.4 or less. Growth in fluid or semifluid media is enhanced by serum and dependent on the presence in the medium of a fermen-

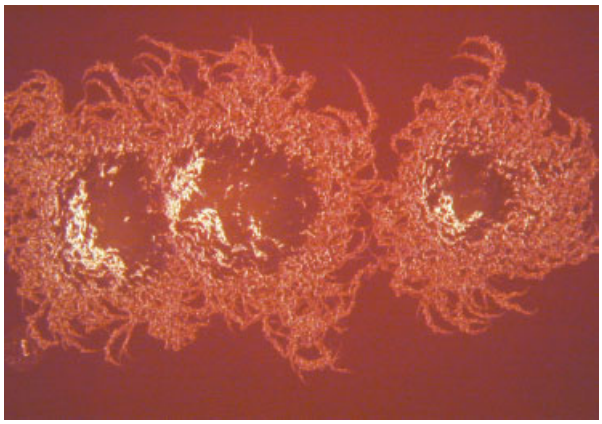

Figure 2 L. buccalis *colonies of 48 h culture (37 °C) on blood agar*

table carbohydrate. Ammonia is not produced. This clearly indicates that carbohydrate is used for energy metabolism. *L. trevisanii* ferments glucose and lactic acid is the major organic end product (Tee et al. 2001).

CELL-WALL COMPOSITION

L. buccalis has a gram-negative cell-wall structure. The diamino acid of the peptidoglycan is *meso*-diaminopimelic acid (Vasstrand et al. 1982). The cellular fatty-acid composition is similar to that of the fusobacteria, with hexadecanoic, octadecanoic, and 3-hydroxytetradecanoic acids as major components (Hofstad and Jantzen 1982). The MIDI (Microbial ID, Inc., Newark, DE, USA) system identified the most abundant cellular fatty acids as $C_{16:0}$ (32–59 percent) and $C_{18:1}$-*cis* 11/t9/t6 fatty acids or an unidentified compound with equivalent chain length of 17.8 (21–42 percent) (Eribe et al. 2002). $C_{12:0}$ (3–16 percent), $C_{15:0}$ DMA or 3-OH-$C_{14:0}$ (4–14 percent), $C_{14:0}$ (3–20 percent), and $C_{16:1}$-*cis* 9 (1–5 percent) were also detected. Seventy percent of the strains contained $C_{18:1}$ –*cis* 9 (1–9 percent) and 62 percent $C_{18:2}$ –*cis* 9,12 (1–6 percent).

LABORATORY ISOLATION AND IDENTIFICATION; SUSCEPTIBILITY TO ANTIBACTERIAL AGENTS

L. buccalis can be isolated from clinical specimens by cultivation anaerobically on blood agar, for instance Brucella blood agar or FAA supplemented with sheep or horse blood. Addition of josamycin, vancomycin, and norfloxacin to the blood-agar medium is recommended for isolation of *L. buccalis* from normal flora. Others use Fusobacterium egg yolk agar for the recovery of *Leptotrichia* (Murray and Citron 1991). A reliable identification can be made from cellular and colonial morphology and a few biochemical tests (Table 1, p. 5).

L. buccalis is susceptible to β-lactam antibiotics, carbapenems, clindamycin, chloramphenicol, tetracyclines, and metronidazole, but resistant to vancomycin and aminoglycosides (George et al. 1981; Weinberger et al. 1991). Most strains are moderately resistant or resistant to erythromycin. The *L. trevisanii* isolate was susceptible to penicillin, metronidazole, and tetracycline, partly resistant to clindamycin, and resistant to erythromycin and gentamycin (Tee et al. 2001).

PATHOGENICITY

Infections with *L. buccalis* are uncommon. Relatively few cases have been described including endocarditis (Hammann et al. 1993; Duperval et al. 1984) and sepsis occurring in immunocompromised, neutropenic patients with mucositis or periodontitis (Reig et al. 1985; Weinberger et al. 1991). The oral cavity may be the source of such infections with the portal of entry being via gingivitis or oral mucosal lesions. The pathogenetic mechanisms of *Leptotrichia* infections are unknown.

INTRODUCTION

Mycoplasmas are distinguished phenotypically from other bacteria by their minute size and total lack of a cell wall. Taxonomically, the lack of cell walls is used to separate mycoplasmas from other bacteria in a class named Mollicutes (*mollis*, soft; *cutis*, skin, in Latin). The current classification of Mollicutes and the properties distinguishing the established taxa are presented in Table 1. While the trivial terms mycoplasmas or mollicutes have been used interchangably to denote any species included in Mollicutes, the trivial names ureaplasmas, entomoplasmas, mesoplasmas, spiroplasmas, acholeplasmas, asteroleplasmas, and anaeroplasmas are routinely used for members of the corresponding genus. Molecular characterization of the uncultured plant and insect mycoplasma-like organisms (MLO) has provided strong experimental support for their inclusion in the class Mollicutes (see Phylogeny and taxonomy). Consequently, the trivial term phytoplasmas has been proposed to replace the awkward name mycoplasma-like organisms. About 200 established species have already been described within the class Mollicutes, and this number continues to rise, including the still uncultured mollicutes, such as the phytoplasmas and the hemotrophic parasites *Haemobartonella* and *Eperythrozoon* species, recently identified as mollicutes and given the trivial name hemoplasmas (Neimark et al. 2001). The potential number of mollicute species is apparently enormous in light of the most prevalent occurrence of mollicutes in insects as each insect species may have its own unique mollicute flora (Tully and Whitcomb 1992).

The interested reader is referred to a number of books on various aspects of mycoplasmology published during the last decade or so (Maniloff et al. 1992; Razin and Tully 1995; Tully and Razin 1996). The most recent multi-authored treatise covering the molecular biology and pathogenicity of mycoplasmas was published in the summer of 2002 (Razin and Herrmann 2002). Several recent general reviews on the molecular biology, genetics, and pathogenicity of mycoplasmas are also available (Baseman and Tully 1997; Dybvig and Voelker 1996; Razin et al. 1998).

CYTOLOGY

Cellular morphology and cytoskeletal elements

The total lack of a cell wall explains many of the unique properties of the mycoplasmas, such as sensitivity to osmotic shock and detergents, resistance to penicillin, and formation of peculiar fried-egg shaped colonies (Figure 1). Thin sections of mycoplasmas reveal that the cells are built essentially of three organelles: the cell membrane, ribosomes, and a circular densly packed double-stranded DNA molecule, the typical prokaryotic genome (Figure 2). Being devoid of a cell wall, mycoplasmas appear gram-negative when stained by the

Table 1 *Major characteristics and taxonomy of the class Mollicutes*[a]

Classification	No. recognized species	Genome size (kb)	Mol% G + C of genome	Cholesterol requirement	Distinctive properties	Habitat
Mycoplasmataceae						
Genus I: *Mycoplasma*	107 (11)[b]	580–1 350	23–40	Yes	Optimum growth 37°C	Humans, animals
Genus II: *Ureaplasma*	7	760–1 170	25–30	Yes	Urease positive	Humans, animals
Entomoplasmataceae						
Genus I: *Entomoplasma*	6	790–1 140	27–29	Yes	Optimum growth 30°C	Insects, plants
Genus II: *Mesoplasma*	12	870–1 100	27–30	No	Optimum growth 30°C	Insects, plants
Spiroplasmataceae						
Genus I: *Spiroplasma*	34	780–2 220	24–31	Yes	Helical filaments	Insects, plants
Acholeplasmataceae						
Genus I: *Acholeplasma*	14	1 500–1 650	26–36	No	Optimum growth 30–37°C	Animals, plant surfaces
Anaeroplasmataceae						
Genus I: *Anaeroplasma*	4	1 500–1 600	29–34	Yes	Obligate anaerobes, oxygen sensitive	Bovine-ovine rumen
Genus II: *Asteroleplasma*	1	1 500	40	No		
Undefined taxonomic status: Phytoplasma	ND[c] (7)	530–1 350	23–29	ND	Uncultured in vitro	Insects, plants

ND, not determined.
a) Updated and modified from Razin et al. (1998).
b) The number of *Candidatus* species is given in parentheses and includes the haemoplasmas (*Eperythrozoon* and *Haemobartonella*) recently transferred to the genus *Mycoplasma*.
c) The taxonomic status of the uncultured phytoplasmas has not been finally defined; seven *Candidatus* Phytoplasma species have so far been published.

Gram stain. Bounded by a plastic cell membrane only, the dominating shape of a mycoplasma cell is a sphere (0.3–0.8 μm in diameter). However, cells of many mollicutes exhibit a variety of morphological entities, including pear-shaped cells, flask-shaped cells with terminal tip structures, filaments of varying length (some branching), as well as helical filaments (Figures 3–5). Maintaining such shapes in the absence of a rigid cell wall has indicated long ago the presence of a cytoskeleton in mycoplasmas (Razin 1978).

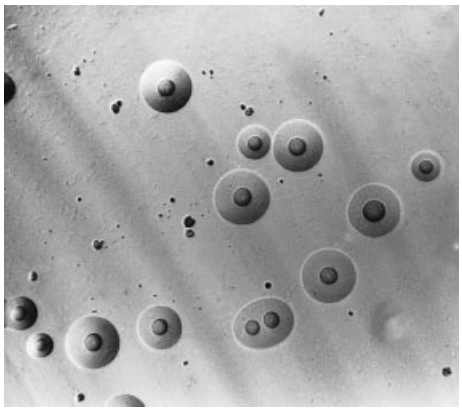

Figure 1 A. laidlawii *colonies on mycoplasma agar (×50) showing the characteristic 'fried-egg' shape, consisting of a central zone embedded in the agar and a peripheral zone on the agar surface.*

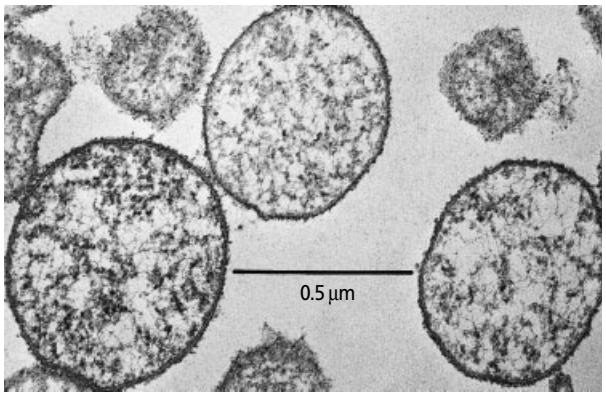

Figure 2 *Electron micrograph of thin-sectioned mycoplasma cells. The cells are bounded by a single membrane exhibiting the characteristic trilaminar shape of sectioned biomembranes fixed in osmium tetroxide. The cytoplasm contains thin threads representing the sectioned chromosome, and dark granules representing ribosomes.*

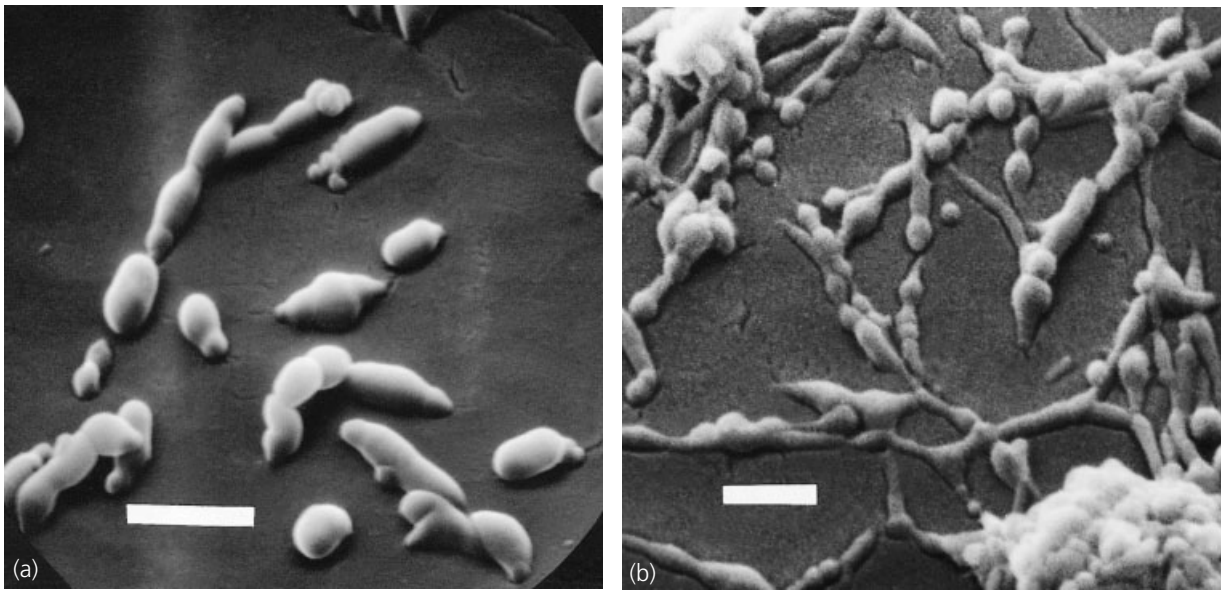

Figure 3 (a) *Scanning electron micrograph of* M. gallisepticum *cells showing the polymorphic shape of the organisms.* **(b)** M. pneumoniae *showing the characteristic elongated cells with tapered tips, as well as spherical cells and microcolonies. Bar = 1 μm.*

An important group of pathogenic mycoplasmas, including *M. pneumoniae* and *M. genitalium*, shares a flask- or club-like cell shape with a protruding tip or bleb structure (Figure 6). These mycoplasmas attach to eukaryotic cells via the tip structure, serving as an attachment organelle (Figure 7; see Adhesion to host cells). Scanning- and transmission-electron microscopy of *M. pneumoniae* cells grown on grids treated with 1 percent Triton X-100 revealed a rod-like tip structure and a network of filamentous strands. Proteins of this so-called 'Triton shell' are apparently cytoskeleton-forming or cytoskeleton-associated proteins (Razin and Jacobs 1992). The cytoskeleton-like structure is thought to function in modulating cell shape, and participate in cell division, gliding motility, and the proper localization of cytadhesins on the mycoplasmal cell surface. Studies by Mayer et al. (1998) suggest that the mollicutes may not be the only bacteria known to possess an internal cytoskeleton.

The genomic analysis of *M. pneumoniae* (Himmelreich et al. 1996) has enabled the identification and molecular characterization of the major protein building blocks of the cytoskeleton of this mycoplasma. Some of these proteins function as surface exposed cytadhesins, while others maintain the proper distribution and/or disposition of the cytadhesins on the mycoplasma membrane, consistent with their presumed scaffolding role (Balish and Krause 2002; Krause and Balish 2001). Recent analysis of the 'Triton shell' by 2D-PAGE and mass spectrometry revealed about 100 protein spots. Regula et al. (2001) identified 41 of them. The identified proteins belonged to several functional categories, mainly energy metabolism, translation, and heat-shock

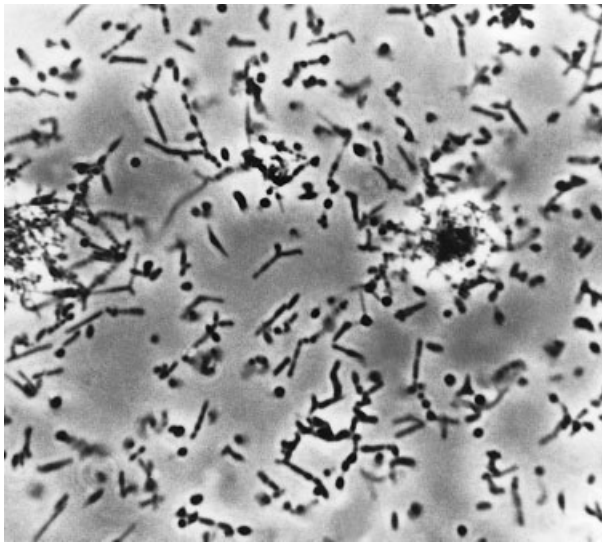

Figure 4 *Phase-contrast light microscopy of* A. laidlawii *cells. Branching filaments and chains of cocci can be seen in these unfixed live broth cultures. Magnification ×1 250.*

Note the broadened headlike structure (arrowheads), with no surface layer (Kirchhoff et al. 1984).*

response. In addition, lipoproteins, and most of the proteins involved in cytadherence were found in this fraction (see Adhesion to host cells section and Table 5). Quantitatively, the most prevalent proteins were the heat-shock protein DnaK, elongation factor Tu and subunits α and β of the pyruvate dehydrogenase complex (Regula et al. 2001). Thus, the 'Triton shell' consists of a very heterogenous complex of proteins as could perhaps be expected from a complex cell fraction isolated according to its insolubility at a low concentration of the mild detergent Triton X-100.

Motility

Most mycoplasmas are nonmotile and have no flagella. However, some of the flask-shaped *Mycoplasma* species, including the human and animal pathogens, *M. pneumoniae*, *M. genitalium*, *M. gallisepticum*, *M. pulmonis*, and *M. mobile* exhibit gliding motility on liquid-covered surfaces. *M. mobile*, isolated from fish gills, is the fastest (2.0–4.5 μm/s, which is up to seven times its cell length per second). The mechanism of this peculiar gliding motility is still unknown (Miyata 2002). Although *M. pneumoniae* is motile and exhibits chemotactic behavior, gliding motility genes could not be identified in this mycoplasma, as it is not yet known which genes have to be looked for. Furthermore, none of the components of the chemotactic signal pathway, the Che proteins, which are well conserved among bacteria, as well as any other 'two-component signal transduction system' could be identified in the sequenced *M. pneumoniae* and *M. genitalium* genomes (Himmelreich et al. 1996).

The gliding force of *M. mobile* responsible for the thrust forward reaches up to 27 pN, which is five to seven times higher than that of motor proteins such as

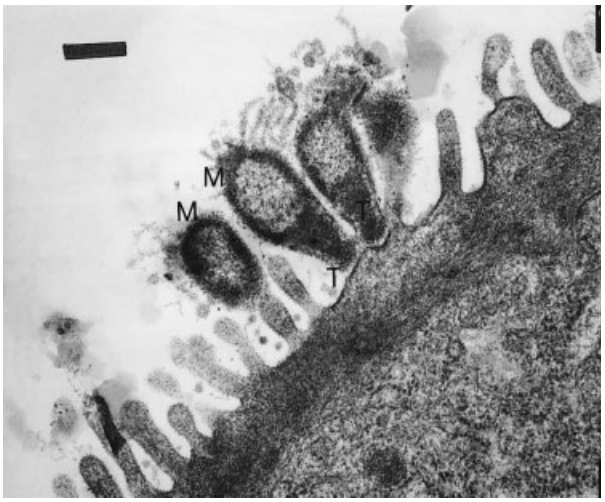

Figure 7 *Thin sections of* Mycoplasma gallisepticum *attaching to tracheal epithelium of chicken 7 days postinfection. The mycoplasmas can be seen to attach through their blebs.* M. mycoplasma*; T, attachment tip. Bar = 0.5 μm. Courtesy of Dykstra and Levisohn.*

myosin and kinensin (Miyata et al. 2002). The force estimate was achieved by trapping gliding *M. mobile* cells, with an attached polystyrene bead, by optical laser tweezers. The ability of the gliding mycoplasmas to cytadhere closely mirrors their ability to bind to glass, a prerequisite for gliding. Because cytadherence is linked to the tip structure it is likely that this attachment organelle plays a major role in the gliding mechanism. In fact, the gliding mycoplasmas always move with the attachment tip organelle at the leading end (Miyata 2002).

Spiroplasma species are unique among mollicutes in having helical morphology (Figure 5), rotary motility, and chemotaxis. Motility is characterized by rapid spinning along the long axis of the cell as well as by flexional or undulating movements of the helical filaments. The spiroplasma cell can essentially be viewed as a membranal tube (about 0.25 μm in diameter) to which a flat cytoskeletal ribbon made of seven parallel paired fibrils (diameter of individual fibril is 45–50 Å) is attached to the inner side of the cell membrane along the shortest helical line. Both tube and ribbon are mutually coiled into a dynamic helix (Trachtenberg and Gilad 2001). Illustrating the minuteness of mollicutes, the size and shape of a whole spiroplasma cell is roughly that of a bacterial flagellar bundle or that of a single eukaryotic flagellum or cilium. In addition to their bare simplicity and structural minimalism, spiroplasma cells are well-defined dynamic helices, amenable to geometrical analysis carried out by Trachtenberg et al. (2003a). Thus, it appears that the scaffolding and the propulsion functions of the cell wall and flagella are both replaced in spiroplasmas by an internal cytoskeleton that functions as a linear motor as well.

Upon cell lysis by deoxycholate, spiroplasmas release the fibrils which consist of a 59 kDa protein. The gene for this protein (*fib*) has been cloned, facilitating the characterization of the structural features of the fibril protein (Williamson et al. 1991). The 59 kDa protein has an equivalent sphere diameter of about 50 Å. Trachtenberg and Gilad (2001) suggest that the fibril protein forms a tetramer, and the tetramer assembles further into flat fibril pairs, seven of which form a flat, monolayered well-ordered ribbon. This structure may function as a linear motor driven by differential and coordinated length changes of the fibrils due to conformational changes of the tetrameric subunits, the shape of which changes from near circular to elliptical. This is the first linear motor described in swimming prokaryotes (Trachtenberg et al. 2003b; Gilad et al. 2003). Berg (2002) takes this point further by proposing a simple way for the ribbon to function in propulsion through bending about two axes in a cyclic manner. The primary effect of this cycle is to roll the spiroplasma cell about its longitudinal axis clockwise. In a viscous medium the helix screws its way like a corkscrew.

Some information on a gene involved in *S. citri* motility has been obtained through transposon mutagenesis (Jacob et al. 1997). An *S. citri* nonmotile mutant was generated by Tn*4001* mutagenesis. The transposon was shown to be inserted into a gene named *scm1*, encoding a putative polypeptide of about 45 kDa with no significant homology to any known protein. The protein was predicted to contain a signal peptide and 10 transmembrane α-helices and a leucine zipper motif. The *scm1* gene was recovered from the wild motile strain, and inserted into an *S. citri* cloning vector. Transfection of the nonmotile mutant with this recombinant plasmid restored motility, indicating that the *scm1* gene product is indeed involved in *S. citri* motility, probably serving as an anchor of the cytoskeletal ribbon to the membrane (Trachtenberg and Gilad 2001). Interestingly, the nonmotile mutant multiplied in the insect vector and was efficiently transmitted to plants, inducing disease. This suggests that spiroplasma motility may not be essential for pathogenicity (Duret et al. 1999).

Cell division

The mode of reproduction of mycoplasmas is essentially not different from that of other prokaryotes dividing by binary fission. The velocity of the DNA replication fork progression in *M. capricolum* was about 6 kb/min, about ten times slower than that of *E. coli*. The time required for one round of chromosome replication was estimated to be about 94 min, and *M. capricolum* is considered among the fastest growing mollicutes (Seto and Miyata 1998). For typical binary fission to occur, cytoplasmic division should be synchronized with genome replication, but in mycoplasmas cytoplasmic division may lag behind genome replication, resulting in the formation of multinucleate filaments. The transformation of mycoplasma filaments into chains of cocci followed by

microcinematography revealed the appearance of constrictions in the cell membrane at about equal distances along the entire length of the filament, a process taking a few minutes (Bredt et al. 1973). While the outline of DNA replication in mycoplasmas is presumably similar to that of walled bacteria, the coupling of chromosome replication and cell division in mycoplasmas is not so simple. The lack of a peptidoglycan layer, which plays important roles in nucleoid partitioning and cell division, argues that the concepts developed for walled bacteria cannot be simply applied to mycoplasmas (Seto and Miyata 1999). Nucleoid movement occurs in combination with cell elongation, but the kind of force that propels and localizes the nucleoids is not known. Mycoplasma cells apparently lack a solid structure like the periseptal annulus in *E. coli*, because they do not have the peptidoglycan layer. It is possible that the fibrillar cytoskeletal structure observed in *M. pneumoniae* and *M. gallisepticum* is involved in nucleoid migration (Seto and Miyata 1999).

The recent sequencing of several mycoplasma genomes (see Genome sequencing section) has provided some information on mycoplasmal genes homologous to cell division genes of wall-covered bacteria. The most important finding, perhaps, is that of the *ftsZ* gene in mycoplasmas (Bork et al. 1995; Fraser et al. 1995; Himmelreich et al. 1996; Wang and Lutkenhaus 1996; Kukekova et al. 1999). In eubacteria the FtsZ protein is a polymer-forming, guanosine triphosphate (GTP)-hydrolyzing protein with tubulin-like elements; it is localized to the site of septation and forms a constricting ring (the Z ring) between the dividing cells. The finding of *ftsZ* in mycoplasmas indicates that it is a highly conserved and ubiquitous gene fulfilling a key role in prokaryote cell division. However, generalizations are risky as *ftsZ* could not be found in *Ureaplasma urealyticum* (Glass et al. 2000) or chlamydia (Galperin 2001). Of the additional genes associated with cell division in eubacteria (*ftsA*, *ftsH*, *ftsI*, *ftsQ*, *ftsW*, *ftsY*) *ftsH* was identified in *M. pneumoniae* (Himmelreich et al. 1996) and *M. capricolum* (Bork et al., 1995), and *ftsY* in *M. genitalium* (Fraser et al., 1995), *M. pneumoniae* (Himmelreich et al. 1996), and *U. urealyticum* (Glass et al. 2000). Applying the proteome approach, Wasinger et al. (1995) proposed the presence of a tubulin-like protein in *M. genitalium*. It has been suggested that the FtsZ protein of prokaryotes is a tubulin homolog, but the tubular structures formed by FtsZ in vitro are substantially different from microtubules, and sequence similarity between FtsZ and tubulin is barely significant (Gupta and Soltys 1996).

An integral part in cell division concerns chromosome replication and segregation into daughter cells. Chromosome replication and partitioning in mollicutes follows the basic principles of binary fission (Miyata and Seto 1999; Miyata 2002). Mycoplasmas carry topoisomerases (see DNA replication and repair section) capable of relaxing superhelical DNA, fulfilling an essential role in cell division (Bailey et al. 1996). In *Mycoplasma* species possessing a tip structure, duplication of this organelle is a prerequisite for cell division. Observation of the cell division process in *M. pneumoniae* suggests that the nascent organelle is formed next to the old one and then migrates to the opposite cell pole before binary fission of the cell takes place (Seto et al., 2001). What is the motive force propelling the migration of the tip organelle? This is certainly an intriguing question for which we have no answer as yet. One possibility is to associate it with the gliding motility of this mycoplasma. Another possibility is to associate it with the filamentous structures taking part in the cell division process (Seto et al. 2001). In conclusion, it appears that on the whole we are still rather far from a clear understanding of the factors coordinating the cell division process in mollicutes, as relevant genetic information has just started to accumulate and is still too fragmentary to be analyzed and evaluated in depth.

CULTIVATION

Several host and cultural factors are important in primary isolation and maintenance of mycoplasmas during early passage levels. These include the chemical and physical suitability of the culture medium, the number of organisms in the tested specimen, and the presence of toxic or inhibitory substances in the inoculum (Taylor-Robinson and Tully, 1998; Tully and Whitcomb 1992). The use of thallium acetate and antibiotics in culture media has made mycoplasma isolation possible in the presence of a variety of other competing organisms in the tested material. Penicillin (500–1 000 units/ml) and polymyxin B (500–1 000 units/ml) have been the drugs of choice for inhibition of either gram-positive or gram-negative prokaryotes and fungi, respectively. Mycoplasmas can often be isolated from diluted but not undiluted infected tissue extracts, suggesting that inhibitors are present in host tissues, like lysolecithin, antimycoplasmal antibodies, and antibiotics (Taylor-Robinson and Tully 1998). It is advisable, therefore, to perform serial dilutions of such extracts in fresh culture media in all primary isolation attempts. Early broth passages of newly isolated mycoplasmas are likely to require prolonged incubation periods, in comparison to the shorter time required for strains well adapted to a particular medium.

The first indication of mycoplasma growth in primary broth cultures is often a slight to moderate pH change of the medium, and in most instances, slight turbidity. Phase-contrast and dark-field microscopy may be effective in monitoring broth cultures, particularly in the case of the motile helical spiroplasmas (Tully and Whitcomb 1992). Checking the agar cultures for the typical fried-egg colonies under a stereomicroscope is the next step. Frequently, the shape of the colonies is not typical

(Taylor-Robinson and Tully 1998). Thus the motile spiroplasmas may form diffuse colonies on the fresh agar surface, lacking the agar-embedded central zone. By increasing the agar concentration, the free water film on the agar surface decreases in thickness. This impedes spiroplasma motility in the film, resulting in the formation of fried-egg colonies (Tully and Whitcomb 1992).

Culture media

A major impediment to mycoplasma research and laboratory diagnosis has been the difficulty of their in vitro cultivation. There is a consensus that only a minority of the mycoplasmas existing in nature have been cultivated so far. For example, despite many efforts for over 30 years, none of the phytoplasmas infecting insects and plants has been cultivated in vitro in an axenic culture (Seemuller et al. 2002). Some of the cultivable mycoplasmas, such as the human respiratory pathogen *M. pneumoniae*, grow very slowly (2–3 weeks incubation at 37°C), particularly on primary isolation. Others, like *U. urealyticum*, grow very fast in vitro, but growth stops abruptly at titers of 10^6–10^7 colony-forming units (cfu) per milliliter compared to 10^9–10^{10} cfu/ml in logarithmic cultures of well-growing mycoplasmas (Razin 1978). The recent mycoplasma genome sequencing projects have provided definitive genetic explanations to the above-mentioned difficulties by demonstrating the remarkable scarcity in mycoplasmas of genes involved in biosynthetic pathways (see Genome sequencing section).

To overcome the assimilative deficiencies of the mycoplasmas, complex media are used for their cultivation. The media are usually based on beef heart infusion, peptone, yeast extract, and serum with various supplements. Efforts to replace the serum component have been continuously made with the aim of reaching a defined growth medium. Serum has been shown to provide, among other nutrients, fatty acids and cholesterol, required for membrane synthesis, in an assimilable nontoxic form. Efforts to substitute the serum component by albumin, fatty acids, and cholesterol solubilized in Tween 80, or by liposomes made of phospholipids and cholesterol, supplemented with serum albumin to neutralize free fatty acid toxicity, have been continued with only limited success (Razin 1978). Nevertheless, several defined culture media were developed for a few fermentative mycoplasmas. The media contain a complex assortment of amino acids, nucleic acid precursors, lipids, vitamins, inorganic ions, together with glucose as an energy source (Hackett et al. 1987). Detailed composition of media for mycoplasmas can be found in the section on cultivation and nutrition in *Methods in mycoplasmology* (Razin and Tully 1983), in Tully and Whitcomb (1992), and in *Molecular and diagnostic procedures in mycoplasmology* (Razin and Tully 1995).

Although the numerous nutritional requirements of mollicutes dictate the need for complex growth media, the notion that the richer the medium the better, may be wrong. It appears, at least in some cases, that the lack of growth of a mycoplasma in a rich medium is not the result of the lack of a specific nutrient, but is rather due to the presence of a component(s) toxic to the mycoplasma. Some *M. hyorhinis* strains, common contaminants of cell cultures, have been known to resist cultivation on conventional mycoplasma media, leading to consider them as particularly fastidious strains. This concept proved to be wrong, as these strains could grow well in a minimal serum-free medium, leading Del Giudice (1998) to suggest that these 'noncultivable' strains are not particularly fastidious, but are more sensitive to inhibitors found in the complex media, mostly as components of peptone and yeast extract. Hence the terms 'noncultivable' and 'fastidious' should be considered as relative terms, that take their meaning only in the context of a specific culture system where growth promoters, and possibly inhibitors, are present.

Generally, mollicutes differ markedly in their atmospheric requirements; while most mollicutes are facultative anaerobes, and usually favor an anaerobic or low-redox-enhanced CO_2 atmosphere on primary isolation, the rumen *Anaeroplasma* and *Asteroleplasma* species are strict anaerobes, very sensitive to oxygen (Table 1). Some mycoplasmas such as *M. hyorhinis* require an aerobic atmosphere. The initial pH of the growth medium should be adjusted to about 8.0 for the fermentative mycoplasmas, and to 6.0–6.5 for the nonfermentative arginine-utilizing mycoplasmas and for the urea-hydrolyzing ureaplasmas. The temperature range for mycoplasma growth varies according to species from about 20–40°C. The optimum temperature for most human and warm-blooded animal mycoplasmas is 36–37°C, while the optimum growth temperature for *M. mobile*, isolated from fish, is 25°C and 30°C for the tortoise mycoplasmas (Brown et al. 2001). Likewise, the optimum temperature for growth of the sterol-requiring entomoplasmas and the sterol-nonrequiring mesoplasmas, isolated from insects and plants, is about 30°C, while the optimum growth temperature of the spiroplasmas and the acholeplasmas lies between 30 and 37°C (Tully et al. 1993).

Cocultivation with cell cultures

A novel approach to improve the chances of in vitro cultivation of fastidious mollicutes is based on coculture with eukaryotic cell lines (cell-assisted growth). In this way, uncultivable spiroplasmas such as the Colorado potato beetle spiroplasma, *S. leptinotarsa*, and the Drosophila sex-ratio spiroplasma, *S. poulsonii*, have been first successfully cocultivated in insect cell lines. Subsequently, primary cultures of these spiroplasmas could be obtained on cell-free media under conditions of low redox potential, enhanced CO_2 atmosphere, and at a pH lower than 7.0, conditions which imitate those

obtained in the insect cell cocultures (Konai et al. 1996). While the use of cocultivation of fastidious spiroplasmas with arthropod cell lines has proved itself in these cases, the choice of an adequate medium for primary isolation and/or subsequent sustained cultivation of these organisms is still much more an art than a science.

Cell-assisted cocultivation, using Vero cell cultures, enabled the cultivation of several strains of the highly fastidious human *M. genitalium* from clinical specimens (Jensen el al. 1996). Also in this case, the mycoplasmas grown in the cell culture (as was indicated by polymerase chain reaction (PCR) monitoring) could be subsequently subcultured in a cell-free medium. The above methodology, as complex as it is, requiring 'heroic' efforts, is certainly inadequate for routine cultivation of fastidious mycoplasmas, leaving the door open for the application of molecular techniques, such as PCR, for detection and identification of fastidious, or the so far uncultivable mycoplasmas (see Diagnosis of infections section).

HABITATS AND ECOLOGY

Mycoplasmas are widespread in nature as parasites of humans (Blanchard and Bebear 2002), mammals (Frey 2002), reptiles (Brown et al. 2001), fish, arthropods, and plants (Seemuller et al. 2002; Tully 1996). The list of hosts known to harbor mycoplasmas is continuously increasing, as does the number of established mollicute species, about 200 so far (Table 1). It is widely agreed that the mollicutes that have already been characterized and taxonomically defined constitute only a part, apparently a minor one, of the mollicutes living in nature (Razin 1992). The higher the number of established mollicute species, the harder it gets to fulfill the minimal requirements for establishing new species (International Committee 1995). A large battery of species-specific antisera and seed are needed for this task. The introduction of molecular tools to taxonomy, including the comparison of 16S rRNA and other conserved gene sequences, genomic restriction patterns, etc. (see Phylogeny and taxonomy and Diagnosis of infections sections) has already been found to be effective in species and strain identification, decreasing the weight of serology in species and strain identification and classification.

Uncultured mollicutes

The successful application of genomic analysis methodology has led to the identification of the uncultured plant and insect MLOs as bona fide mycoplasmas (Phylogeny and taxonomy section), showing the way for confirming the identity of other mycoplasma-like organisms as mollicutes. Thus, the Grey Lung 'virus' disease of mice, caused by an agent resembling mycoplasmas in thin sections of lung material, but resisting cultivation, has been identified as a mycoplasma based on its genome size and 16S rRNA sequence analysis. It has been proposed to classify this organism as '*Candidatus Mycoplasma ravipulmonis*', the '*Candidatus*' taxon being reserved to classification of uncultured prokaryotes (Neimark et al. 1998). Most important is the recent finding, based on 16S rRNA sequence analysis, that *Haemobartonella* and *Eperythrozoon* species, long known as uncultured wall-less pathogenic bacteria, infecting erythrocytes of a wide range of vertebrate hosts, are phylogenetically closely related to Mollicutes rather than to rickettsia, and should, therefore, be reclassified as *Mycoplasma* species (Neimark and Kocan 1997; Rikihisa et al. 1997, see Phylogeny and taxonomy section). The inclusion of these hemotropic agents in Mollicutes represents an entirely new group of pathogens classified as mycoplasmas.

Host and tissue specificity

Mycoplasmas usually exhibit a rather strict host and tissue specificity, probably reflecting their nutritionally exacting nature and obligate parasitic mode of life. However, there are numerous examples of the presence of mycoplasmas in hosts and tissues different from their normal habitats (Tully 1996). The primary habitats of human and animal mycoplasmas are the mucous surfaces of the respiratory and urogenital tracts, eyes, alimentary canal, mammary glands, and joints. The obligatory anaerobic anaeroplasmas have so far been found in the bovine and ovine rumen only (Table 1). Spiroplasmas and phytoplasmas are widespread in the gut, hemocoel, and salivary glands of arthropods. The spiroplasmas and phytoplasmas may be introduced through sap-sucking insects to the phloem tissues of plants, causing disease (Tully and Whitcomb 1992; Seemuller et al. 2002). Accompanying the increasing numbers of patients suffering from various types of immunodeficiencies, associated with hypogammaglobulinemia, AIDS, treatment with immunosuppressive medication in patients undergoing organ transplantation, more and more reports appear on the isolation of mycoplasmas from organs different from their usual habitats. Thus, mycoplasmas and ureaplasmas belonging to the normal urogenital flora have been isolated from the blood of patients suffering from AIDS or treated with immunosuppressive drugs. Hypogammaglobulinemic and immunocompromised patients become susceptible to infections by the urogenital mycoplasmas *M. hominis* and *U. urealyticum*, spreading into organs such as the respiratory tract and joints (Frangogiannis and Cate 1998; Gass et al. 1996) causing disease in these organs.

Mycoplasmas infecting cell cultures

Cell cultures infected by mycoplasmas constitute an artificial habitat. The serious problems created by the

persistent and hard to detect infections of cell cultures are reflected in the voluminous literature on this subject. Reports from various countries show that 10–87 percent of cell cultures are infected by mycoplasmas (Barile and Rottem 1993; Uphoff and Drexler 2002). The percentage of infected cell cultures depends to a large extent on the population of cell cultures assayed, on the control practices used, and on the efficiency of the assay procedures applied. The *Mycoplasma* species infecting cell cultures have remained essentially the same over the years. *M. hyorhinis*, *M. orale*, *M. arginini*, and *A. laidlawii* being the dominant contaminants. The increasing percentage of cell cultures infected by *M. fermentans*, a mycoplasma incriminated as a cofactor in AIDS and rheumatoid arthritis (see Pathogenicity section), is of particular interest regarding the possible origin of contamination. Elimination of mycoplasmas from infected cell cultures by antimycoplasmal agents is time consuming and is often unsuccessful (Uphoff et al. 2002) probably due to the intracellular location of a small percentage of the contaminating mycoplasmas.

Human and animal mycoplasmas

Table 2 lists the mycoplasmas found in humans. Some of these mycoplasmas may cause disease while others are commensals, constituting part of the normal flora of the oropharynx and the urogenital tract. Some of the human mycoplasmas shown in Table 2 can also be isolated from nonhuman primates. Farm animals, cattle, sheep, goats, horses, swine, chickens, and turkeys harbor a great variety of mollicutes, many of them pathogenic. Mollicutes can also be found in dogs, cats, and small laboratory animals, either as commensals or pathogens. A mollicute flora has been defined in a wide variety of wild animals, including elephants, lions, seals, crocodiles, turtles, and prawns. In essence, mollicutes may be ubiquitous in the animal world. It appears as though the main factor for adding an animal to the long list of animals harboring mycoplasmas is the willingness of a mycoplasmologist to invest the effort required to isolate and characterize mycoplasmas from the animal. Interestingly, the laboratory rabbit represents an exception to this rule, as it appears to be free of mycoplasmas. Lack of a natural mycoplasma flora makes the rabbit a preferred animal for production of specific antisera to mycoplasmas. For detailed descriptions of the mollicute flora of humans and animals see the relevant chapters in *Molecular biology and pathogenicity of mycoplasmas* (Razin and Herrmann 2002).

Mycoplasmas in arthropods and plants

Arthropods are major habitats of mollicutes, including the helical spiroplasmas, sterol-nonrequiring mesoplasmas, sterol-requiring entomoplasmas, and the uncultured phytoplasmas (Table 1). All spiroplasmas are obligately associated with insects, either as commensals, pathogens or mutualists, and may constitute one of the largest microbial genera as a result of their diversification and coevolution with their arthropod hosts (Gasparich 2002).

Spiroplasmas are most frequently found in the insect gut, less frequently in the hemolymph, and occasionally in various organs such as the salivary glands. Spiroplasmas in the insect gut are generally acquired by natural feeding, either from plant tissue, from nectar, or from ingestion of other insects. Some spiroplasmas, like the honeybee spiroplasmas, are pathogenic and may kill their insect hosts, or eliminate the male progeny of infected Drosophila (Williamson et al. 1999), while others are considered commensals, even when present in large numbers in the hemolymph. Spiroplasmas involved in vector-transmitted plant diseases (citrus stubborn, corn stunt) must pass through a complex biological cycle that involves uptake from the sieve cells of the plant phloem and subsequent passage to, or multiplication in, the insect alimentary tract, gut epithelium, basement membrane, hemocoel, and possibly some internal organs. The spiroplasmas apparently enter into insect cells by receptor-mediated endocytosis. In this process the spiroplasmas lose their helicity, and appear as rounded, pleomorphic bodies with a reticulated internal

Table 2 *Site of colonization and pathogenicity of human mollicutes*

Species	Primary site of colonization	Pathogenicity
M. pneumoniae	Lung, oropharynx	Primary atypical pneumonia
M. genitalium	Urogenital tract	Nongonococcal urethritis
M. hominis	Urogenital tract	Usually commensal, may cause infections on reaching internal organs (salpingitis)
M. fermentans	Urogenital tract, respiratory tract	Cofactor in AIDS activation? Arthritis?
M. penetrans	Urogenital tract? Colon?	Cofactor in AIDS activation?
M. salivarium	Buccal cavity	Commensal. Periodontal disease?
M. orale	Buccal cavity	Commensal
Ureaplasma urealyticum	Urogenital tract, placenta	Nongonococcal urethritis, neonatal lung and brain infections

Commensal mycoplasmas less commonly isolated from humans: *M. buccale*, *M. faucium*, and *M. lipophilum* from the oropharynx; *M. primatum* and *M. spermatophilum* from the genitals, and *M. pirum* from blood (see Blanchard and Bebear 2002).

structure, most frequently found in membrane-bound pockets in the insect cell (Kwon et al. 1999). The organisms eventually pass from the hemocoel into the ciliary cells and salivary duct, from which reinoculation of healthy plants takes place. Induction of disease in the plant is the rule. The symptoms in plants include chlorosis, leaf mottling, proliferation of growing points, and general stunting (Tully and Whitcomb 1992).

A rather intriguing issue concerns the possible occurrence and pathogenicity of spiroplasmas in animals. Only one spiroplasma, *S. mirum* strain SMCA has been shown to experimentally infect suckling mice causing cataracts (Gasparich 2002). Claims associating spiroplasmas with transmissible human spongiform encephalopathies have been repeatedly made, the most recent claim being based on positive PCR tests for *S. mirum* 16S rDNA in human brain samples (Bastian and Foster 2001). Spiroplasma-like structures could also be demonstrated in a cataract in a premature baby, a finding supported by positive PCR with the 16S rDNA of *Spiroplasma* group VI (Lorenz et al. 2002). The above findings may be considered at most suggestive, but appear worthy of further study.

The nonhelical mollicutes of the genera *Entomoplasma* and *Mesoplasma* have been found as inhabitants of the insect gut (fireflies, beetles, horseflies, moths, butterflies, and bees). However, some entomoplasmas and mesoplasmas have also been identified on plant surfaces, so that most species in either group can be acquired from various plant surfaces or flowers through insect visitation and feeding excursions (Tully 1996). The largest group of mollicutes inhabiting plants are the uncultured plant-pathogenic phytoplasmas. These mollicutes are transmitted primarily by phloem-feeding leafhoppers and are the causative agents of more than 300 different plant 'yellows' diseases and the list continues to grow. Plants infected by phytoplasmas exhibit an array of symptoms that suggest profound disturbances in the normal balance of plant hormones or growth regulators. Symptoms include virescence (green flowers), phyllody (floral parts develop into leafy structures), sterility of flowers, proliferation of auxilliary shoots (witches broom appearance), abnormal elongation of internodes resulting in slender shoots, generalized stunting, discoloration of leaves and yellowing (Lee et al. 2000; Seemuller et al. 2002).

PHYLOGENY AND TAXONOMY

Phylogeny

The early studies of Woese et al. comparing 16S rRNA sequences of mollicutes have provided the basis for mycoplasma phylogeny. Accordingly, the mycoplasmas arose at a node on the branch of gram-positive bacteria having a low G + C genome. This branch of the *Lactobacillus* group contains *Lactobacillus*, *Bacillus*, and *Streptococcus* species. The closest to mycoplasmas on this branch is a small subgroup of clostridia represented by *Clostridium innocuum* and *C. ramosum* (Figure 8).

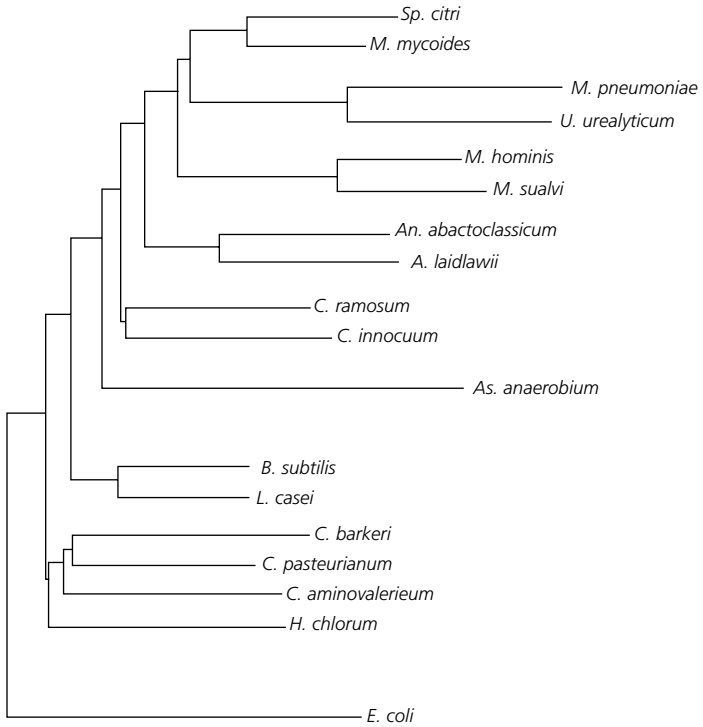

Figure 8 *Schematic dendrogram presentation of the phylogenetic relationship of Mollicutes to some related eubacteria based on 16S rRNA sequences.*

Mycoplasma phylogeny from this node took place by degenerate or reductive evolution, characterized by a rapid tempo, in line with the marked genotypic and phenotypic variability characterizing the mollicutes as a group (Woese 1987). Phylogenetic trees of Mollicutes are still based mostly on 16S rRNA sequences, but several other conserved gene sequences, such as *tuf* genes have been used for this purpose (Kamla et al. 1996). According to 16S rRNA sequences, the Mollicutes are divided into five phylogenetic units (clades): the asteroleplasma, spiroplasma, pneumoniae, hominis, and anaeroplasma clades (Johansson and Pettersson 2002; Maniloff 2002; Weisburg et al. 1989).

A scheme of mycoplasma evolution has been proposed by Maniloff (2002). Accordingly, the ancestral mycoplasma arose from the *Streptococcus* phylogenetic branch about 600 million years ago, having probably a genome of about 2 000 kb. The mycoplasma branch split later into two major branches: one branch led to the *Asteroleplasma*, *Anaeroplasma*, and *Acholeplasma* branches, and the other led to the *Spiroplasma*, *Entomoplasma*, and *Mycoplasma* branches. The phytoplasmas subsequently arose from the *Acholeplasma* branch, and *Ureaplasma* arose from the *Mycoplasma* branch. In both major branches genome reductions had occurred independently during their degenerate evolution. Thus, degenerate evolution of the *Acholeplasma-Anaeroplasma* branch, taking place after the appearance of flowering plants, has led to the phytoplasmas with 600- to 1 200-kb genomes, while evolution of the second major branch produced the *Spiroplasma* branch with 1 000- to 2 000-kb genomes, and the *Entomoplasma*, *Mesoplasma*, *Mycoplasma*, and *Ureaplasma* branches with 600- to 1 200-kb genomes. Clearly, the time at which transition to rapid evolution occurred correlate with major paleontological events in the evolution of the flora and fauna that formed ecosystems for lineages of each branch. Thus, the *Spiroplasma* and *Entomoplasma* transition to rapid evolution occurred about 100 million years ago soon after the appearance of the first flowering plants and their associated insects. The increase in potential hosts presumably provided niches for the selection of new lineages. Although all the above should be taken as hypothetical assessments, they emphasize a cardinal point: the mollicutes are relatively late evolutionary products.

Taxonomy

There is a consensus among bacterial taxonomists that the complete sequences of bacterial genomes will form the basis for phylogeny and, ultimately, taxonomy. Yet, as long as complete genomic sequences are available for a relatively few bacteria only, current bacterial taxonomy, including that of mollicutes (International Committee 1995), relies on the combination of phenotypic characteristics and phylogenetic data based on partial genomic sequences, mostly those of the conserved ribosomal RNA genes. Detailed descriptions and evaluations of current molecular methods in taxonomy, phylogeny, and diagnostics of mollicutes can be found in Razin (1992), in the two volumes of *Molecular and diagnostic procedures in mycoplasmology* (Razin and Tully 1995; Tully and Razin 1996) and in *Mycoplasma protocols* (Miles and Nicholas 1998).

While the availability of complete genomic sequences is expected to provide a sound basis for establishing phylogenetic relatedness among bacterial species and consequently enable the construction of taxonomic entities based on phylogeny, the way to achieve this has not been worked out as yet, as it presents several key problems. Thus, the current somewhat arbitrary and artificial definition of the basic taxonomic entity, that of a bacterial species, includes all strains with approximately 70 percent or higher DNA homology and with 5°C or lower ΔTm (Razin 1992) and over 97 percent sequence similarity of 16S rDNA (Stackebrandt and Schumann 2000). There can be little doubt that this definition will have to be modified once comparison of entire genomic sequences replaces the cumbersome and not too accurate determination of genetic homology based on DNA–DNA hybridization tests. Yet, as long as the number of bacterial genomes sequenced remains small, there is still more than enough time to work out a solution to the above problem. Comparison of the genomic sequences of *M. genitalium* and *M. pneumoniae* (Himmelreich et al. 1997; Herrmann and Reiner 1998) has revealed the significant genomic relatedness of these mycoplasmas, but also underlines the problems taxonomists may face when using comparative genomic data to redefine taxonomic entities, including that of a bacterial species.

Conserved genes as molecular markers

The great weight given to 16S rDNA sequences in mycoplasma phylogeny, taxonomy, and species identification (Razin 1992) has led the International Committee on the Taxonomy of Mollicutes (1997) to recommend the inclusion of the 16S rDNA sequence in any description of a new mollicute species. Johansson has been compiling a database of 16S rDNA sequences of the recognized *Mycoplasma* species deposited at GenBank (Johansson and Pettersson 2002).

A most important contribution of 16S rRNA gene sequences to mollicute phylogeny and taxonomy has been the placing of the uncultured phytoplasmas as a distinct monophyletic clade, within Mollicutes, closely related to the acholeplasmas (Lee et al. 2000; Seemuller et al. 2002). This conclusion has been supported by the small genome size of phytoplasmas, resembling that of the culturable mollicutes (Marcone et al. 1999), by the finding of only two rRNA operons in the phytoplasmas, and a $tRNA^{Ile}$ gene in the spacer region between the 16S

and 23S rRNA genes (Ho et al. 2001; Seemuller et al. 2002), a feature found also in acholeplasmas. The deduced amino acid sequences of some of the highly conserved ribosomal protein genes also indicated that the phytoplasmas are more closely related to *Acholeplasma* than to *Mycoplasma* species, and like acholeplasmas they read UGA as a stop codon rather than a tryptophan codon. Based on comparison of 16S rRNA gene sequences and on sequences of the 16S/23S intergenic spacer regions the phytoplasma clade was divided into 20 subclades (Seemuller et al. 2002). The taxonomic implications of these studies are that the phytoplasmas should be distinguished at the minimal taxonomic level of a genus, and each phytoplasma subclade should represent at least one distinct species (International Committee 1997). However, in the absence of the phenotypic markers used to classify mollicutes, taxonomic affiliations cannot be resolved at the present time in the conventional way. Thus, a provisional classification of the uncultured phytoplasmas has been introduced by applying the *Candidatus* taxonomic category (International Committee 1997). So far seven *Candidatus* species names for phytoplasmas have been published (Table 1; Seemuller et al. 2002).
The phytoplasma case demonstrates well the revolution occurring in bacterial taxonomy, where molecular data suffice for laying the phylogenetic and taxonomic basis for classification of a group of organisms for which very few phenotypic characteristics are available.

The molecular approach to phytoplasma classification has recently also been applied to the uncultured hemoplasmas (Neimark et al. 2001; see Habitats and ecology) comprising of the *Haemobartonella* and the *Eperythrozoon* species. These bacteria have been classified until recently as rickettsiae (order Rickettsiales) due to their small size, staining properties, obligate parasitism, and hemotrophic character. Several of them are transmitted by blood feeding arthropods. However, phylogenetic analyses of 16S rRNA gene sequences have revealed that *Haemobartonella* and *Eperythrozoon* species are not rickettsiae, but are rather mycoplasmas (Neimark and Kocan 1997; Rikihisa et al. 1997) with the highest similarity scores with members of the pneumoniae clade, closest to *M. fastidiosum* and *M. cavipharyngis* (Neimark et al. 2002; Johansson et al. 1999). Since the hemoplasmas have not been cultured as yet, naming of new species should be included in the *Candidatus* category (Neimark et al. 2001, 2002).

The morphology of the hemoplasmas is of small coccoid organisms attached to erythrocytes, while a few may appear free in the erythrocyte cytoplasm. The individual coccoid cells can aggregate to give the appearance of short chains and small clusters of rod-shaped organisms. Electron microscopy shows the coccoid organisms to be about 0.3 μm in diameter with no cell wall. This morphology corresponds well with that of mycoplasmas (Neimark et al. 2002; Messick et al. 2002). Although some *Haemobartonella* and *Eperythrozoon* species can cause overt disease in healthy immunocompetent hosts, the majority of these species produce chronic asymptomatic infections. Clinical disease usually includes hemolytic anemia which varies from mild to severe.

Although the 16S rRNA sequences have proved to be very effective tools in the phylogeny and taxonomy of mollicutes, it has been felt that additional phylogenetic markers are desirable to support the conclusions based on the 16S rRNA data. Generally, 'housekeeping' or constitutive genes, which are expressed in all living organisms because they provide essential functions, such as replication, transcription, and translation, are good candidates for genetic differentiation of species. In fact, such markers have already been applied, including the conserved ribosomal protein genes, the elongation factor EF-Tu (*tuf*) gene, the heat shock protein gene *hsp70*, the *ftsZ* gene, the DNA repair *uvrC* gene, the ribonuclease P (*rnpB*) gene, and the 16S/23SrRNA intergenic sequences (Birkenheuer et al. 2002; Harasawa et al., 2000; Johansson and Pettersson 2002, Razin et al. 1998). Use of these markers has supplemented and complemented the 16S rRNA comparative data. A priori, wobble in the genetic code permits more variations in protein gene sequences, even of highly conserved genes, than is possible in rRNA sequences. Thus, while the ribosomal protein-encoding genes are conserved, they vary in size and primary sequence more than the 16S rRNA genes. Therefore, the ribosomal protein genes have greater potential to reveal variations among closely related strains. Likewise, the intergenic spacer region located between the 16S and 23S rRNA genes, being less subjected to evolutionary constraints than the genes themselves, exhibits greater sequence variation, a property of use in strain differentiation (Harasawa et al. 2000).

Intraspecies genetic heterogeneity

The rather arbitrary and somewhat vague definition of a bacterial species, and even more so the rather frequent and significant chromosomal rearrangements taking place in mycoplasmas (Chromosomal rearrangements section), as well as the rather frequent integration of extrachromosomal elements in the mycoplasmal genome (see Extrachromosomal elements and Insertion-like elements sections) are conducive to the most common finding of genotypic heterogeneity of strains within the same species. Intraspecies genotypic heterogeneity, noticeable through serological testing and electrophoretic analysis of cell proteins, has become much easier to distinguish by applying the much more sensitive molecular tools, such as restriction fragment length polymorphism (RFLP), restriction-modification profiles, conserved gene sequences, and sequence analysis of species-specific protein genes (see Diagnosis of infections section). These tests have provided epidemiolo-

gists with very sensitive tools distinguishing strains of interest in the clinic and in the field. Based on such molecular tools, the clinically important human *Ureaplasma urealyticum*, long known to consist of two clusters of serovars, has recently been divided into two species, *U. urealyticum* and *U. parvum* (Robertson et al. 2002). Another example of clinical importance concerns the difference between the European and African/Australian strains of *M. mycoides* subsp. *mycoides* SC. The African/Australian strains are significantly more virulent than the European strains and cause more serious cases of contagious bovine pleuropneumonia. Recent studies indicate that the chromosome of the European strains lacks an 8.84 kb segment found in the African strains that includes two ORFs of putative ATP-binding cassette (ABC) transporters and several genes encoding membrane proteins and an insertion element. This chromosomal deletion is associated with a deficiency in glycerol uptake and metabolism in the European strains, possibly explaining their lower pathogenicity (Vilei et al. 2000; see Pathogenicity section).

Metabolic and phenotypic markers

The present tendency to depend on direct genomic analysis, made available by the dramatic advancements of molecular genetic methodology, has pushed aside further development of classical taxonomic tools based on determination of nutritional requirements and enzymatic activities (Razin 1992). Even electrophoretic cell protein profiles are now used less extensively as taxonomic tools than in the 1970s and in the early 1980s. The reason being that these profiles reflect the expression of specific genes and are thus liable to changes. It is now possible to clone and sequence the protein genes themselves and thus have a more direct comparative measure. Yet, the recent development of the 'proteome' approach to genomic analysis may revive the use of 2D-electrophoretic patterns of cell proteins as a taxonomic and phylogenetic tool (Weiner et al. 2002).

It should also be pointed out that distinguishing members of the class Mollicutes by their metabolic characteristics has been generally of limited phylogenetic and taxonomic usefulness. There are a few exceptions, including the ability to ferment glucose, hydrolyze arginine and urea, and dependence on cholesterol for growth and anaerobiosis (Razin 1978). Cellular localization of NADH oxidase activity has also been of help in classification of mollicutes at and above the genus level. While *Acholeplasma* species resemble other prokaryotes in having the NADH oxidase localized in the plasma membrane, this enzymatic activity is located in the cytoplasm of *Mycoplasma*, *Spiroplasma*, and *Ureaplasma* species. The finding of this activity in the cytoplasm of the *Mesoplasma* and *Entomoplasma* species has helped to distinguish these newly described genera from *Acholeplasma* species (Pollack et al. 1996; Tully et al. 1993). Extensive studies carried out in Pollack's laboratory (reviewed in Pollack 2002b) were aimed at finding the mycoplasmal enzymatic activities useful for the differentiation of the mollicutes genera. Several activities endowed with such a potential were defined, but so far have not been put into general use.

SEROLOGY

At the species level, serologic relatedness has until recently overshadowed all other features used in routine mollicute identification, but the weight given to determination of molecular properties in mollicute classification and identification is steadily increasing (Razin 1992). The high rate of surface antigenic variation characterizing mollicutes (see Antigenic variation) may impose some limitations on the use of monoclonal antibodies to surface antigens as tools in mycoplasma identification (Rosengarten and Yogev 1996), difficulties usually not encountered when polyclonal antibodies are used (International Committee 1997). In order to limit the number of serological tests and, more so, the large number of specific antisera currently required for the definition of new mollicute species, the International Committee on the Taxonomy of Mollicutes (2001) has agreed that based on 16S rRNA sequences it should be possible to place the new isolate in the proper phylogenetic clade and restrict serological cross-testing to members of this clade only.

CHOLESTEROL REQUIREMENT

The weight given to cholesterol requirement in mollicute taxonomy illustrates well the conflict that may occur between taxonomy based on phenotypic characteristics and that based on molecular phylogenetic data. Cholesterol requirement has been considered for a long time as a major criterion in establishing high taxonomic groupings within the Mollicutes. Recent findings weaken the high status of cholesterol requirement in mollicute classification. Thus, the cholesterol-nonrequiring mesoplasmas, considered previously as acholeplasmas, were shown to possess molecular properties very different from those of the classic acholeplasmas, requiring their taxonomic separation (Pollack et al. 1996; Tully et al. 1993). In addition, several *Spiroplasma* species were recently shown to grow in the absence of cholesterol (Tully et al. 1993). These data suggest that nutritional dependency on exogenous sterols is a trait that has arisen independently several times during the evolution of mollicutes, as it occurs in at least three different phylogenetic groups. It thus appears that cholesterol requirement should not be used as a sole definitive criterion in defining higher taxa of the class Mollicutes, but rather serve as one of a matrix of characters in mollicute classification. Consequently, nutritional requirements, though being the most practical traits to

be assessed in the routine laboratory, may not always be reliable indicators of phylogenetic relationships.

Blending taxonomy with phylogeny

While it is generally agreed that basing bacterial taxonomy on phylogeny is both inevitable and advantageous, there is still disagreement among bacterial taxonomists whether the time is ripe for radical changes in bacterial taxonomy (for detailed discussion see Razin 1992). The taxonomic status of the *Mycoplasma mycoides* cluster illustrates the problem well. The Mollicutes phylogenetic tree based on 16S rDNA sequences has suggested that the *M. mycoides* cluster is phylogenetically related to the genus *Spiroplasma* (Weisburg et al. 1989). However, the proposal to reclassify this cluster accordingly has not been adopted by the International Committee (1997) arguing that such a reclassification would create considerable problems in diagnostic veterinary medicine. Likewise, reassignment of all other *Mycoplasma* species to a new genus would have unacceptable consequences in human and veterinary medicine. For the time being a polyphasic classification based only partly on phylogeny is recommended, striving to fit in as much as possible mollicute taxa into phylogenetic classification.

PHYSIOLOGY

Cell membrane proteins

Lacking a cell wall and intracytoplasmic membranes, the mollicutes have only a single type of membrane, the plasma membrane. The ease with which this membrane can be isolated and the ability to introduce controlled alterations in its composition have made mycoplasma membranes effective tools in membrane research (Razin 1978, 1993).

Proteins constitute over two thirds of the mycoplasma membrane mass; the rest being membrane lipids. The structure and function of mycoplasmal membrane proteins have recently been reviewed by Wieslander and Rosen (2002). Membrane lipoproteins have attracted much attention in recent years as their relative abundance in mycoplasma membranes is most remarkable in contrast to the limited number of lipoproteins in membranes of other eubacteria. Based on characteristic lipoprotein-specific features, Himmelreich et al. (1996) annotated 46 putative lipoprotein genes in the *M. pneumoniae* genome, while 21 lipoprotein genes have been annotated in the *M. genitalium* genome (Fraser et al. 1995; Himmelreich et al. 1997). The 25 additional lipoprotein genes in *M. pneumoniae* are only gene amplifications, which are frequently organized in sequential order (Herrmann and Reiner 1998). The *M. pulmonis* genome encodes 56 lipoproteins (Chambaud et al. 2001) while the *U. urealyticum (parvum)* genome appears to be the richest, encoding 74 lipoproteins (Glass et al. 2000). The unusually high number of lipoproteins in mollicutes may be attributed to the absence of a cell wall and a periplasmic space in these organisms. Mollicutes possess typical eubacterial signal peptides that direct the newly synthesized proteins into a secretory pathway for transport across the cell membrane (Yogev et al. 1991b). Still, the mollicute lipoprotein signal peptides are longer than for any other bacteria, a feature possibly associated with their thicker cholesterol-containing cell membrane, requiring longer transmembrane segments (Edman et al. 1999).

For surface-exposed membrane proteins which have to function on the cell outside, acylation of the proteins by long chain fatty acids is an effective way of anchoring the proteins to the cell surface. Cultivation of mollicutes in the presence of labeled palmitate or myristate labels a significant number of membrane proteins. Interestingly, membrane lipoproteins are amongst the most dominant antigens in mollicutes (Razin et al. 1998; Wieslander and Rosen 2002), and a majority of the mycoplasma cell surface antigens known to undergo antigenic variation are lipoproteins (see Antigenic variation section). At least some mycoplasmal membrane lipoproteins, characterized in *M. pneumoniae*, *M. genitalium*, *M. fermentans*, and *M. hyorhinis*, carry only two fatty acid acyl chains linked to the N-terminal cysteine residue via a thioester linkage between diacylglycerol and cysteine, lacking the third fatty acid linked to the amino group of cysteine, normally found in lipoproteins of other eubacteria. In fact, the transacylase responsible for acylation of the amino group of cysteine could not be identified in the *M. pneumoniae* and *M. genitalium* genomic analysis (Calcutt et al. 1999b; Le Henaff et al., 2001; Himmelreich et al., 1996; Himmelreich et al. 1997; Razin et al. 1998). Yet, chemical analysis of spiralin, the major lipoprotein of *S. melliferum*, showed that in addition to the two ester-linked acyl chains, a third acyl chain is amide linked to the cysteine, resembling the classical eubacterial lipoproteins (Le Henaff and Fontenelle 2000; Le Henaff et al. 2000). Similar findings were reported for the acylated lipoproteins of *M. agalactiae* (Le Henaff et al. 2000).

Molecular genetic methodology has recently enabled the preliminary characterization of membrane proteins of the uncultured phytoplasmas. The phytoplasma membrane proteins characterized thus far are apparently not lipoproteins. They appear to possess cleavable N-terminal signal sequences and an hydrophobic C-terminal anchor. The central hydrophilic domain is located on the outside of the cell membrane (Blomquist et al. 2001; Barbara et al. 2002).

Membrane lipids

Virtually all mycoplasma lipids are located in the cell membrane and, as in other biological membranes, consist

of phospholipids, glycolipids, and neutral lipids. A detailed description of the composition, distribution, and biosynthesis of mycoplasmal membrane lipids can be found in Rottem and Kahane (1993). As mentioned in the Genome sequencing section, the mycoplasmas are partially or totally incapable of fatty acid synthesis, and depend on the host, or the culture medium, for their supply. In addition, most mycoplasmas require cholesterol for growth, a unique requirement among prokaryotes (Rottem 2002b). The fatty acid residues of membrane phospholipids and glycolipids, as well as cholesterol, constitute a major portion of the hydrophobic core of the membrane. The dependence of mycoplasmas on the exogenous supply of fatty acids and cholesterol has been one of their greatest advantages as models for membrane studies. The ability to introduce controlled alterations in mycoplasma membrane lipid composition, simply by controlling the composition and content of fatty acids and sterols in the growth medium, has been used most effectively in elucidating the molecular organization and function of the lipids in mycoplasma membranes (Razin 1993; Wieslander and Rosen 2002).

Almost all recent studies concerning mycoplasma lipid biosynthesis and its regulation were carried out on *A. laidlawii*, an organism which has been used for a long time as a model organism, particularly in studies dealing with the physical state of the membrane (Razin 1978, 1993). It was the organism used by Wieslander, Rilfors, Lindblom and their associates at Umea University to show that altering the polar headgroup structure of membrane phospho- and glycolipids, and changing the acyl chain structure, are the two strategies employed by the organisms to adapt their membrane lipid composition to various environmental and physiological conditions (reviewed by Wieslander and Rosen 2002). A common way in prokaryotes to respond to varying growth temperatures is to regulate the degree of unsaturation of the acyl chains of the lipids. *A. laidlawii* cannot synthesize unsaturated fatty acids, and saturated fatty acids are synthesized by it in very limited amounts, when the organism is grown in a thoroughly lipid-depleted medium. Thus, at least one exogenous fatty acid must be supplied in the growth medium in order for the cells to grow.

A. laidlawii exploits a different mechanism to cope with changes in environmental conditions, namely, by altering the proportion of lipids with different polar headgroups. It has been hypothesized and experimentally supported by the Umea group that *A. laidlawii* strain A-EF22 regulates its membrane lipid composition to maintain a proper balance between lipids forming a lamellar crystalline phase, and lipids forming reversed nonlamellar phases. The first acholeplasmal lipid shown to form a nonlamellar phase was monoglucosyl diacylglycerol (MGlcDAG). The other major glycolipid, diglucosyl diacylglycerol (DGlcDAG) resembles the acholeplasmal phospholipids in solely forming the lamellar phase at all temperatures and with all acyl chain compositions. It was then found that the acholeplasma is capable of varying the proportion of the MGlcDAG and DGlcDAG in response to the prevailing growth conditions (Wieslander and Rosen 2002).

In conclusion, the extensive studies of the Umea laboratory show that several basic features of the membrane homeostasis mechanism in *A. laidlawii*, including the maintenance of phase equilibria, spontaneous curvature, and surface charge density of the membrane lipid bilayer, are dependent upon the physical properties of the bilayer and are sensed by the two consecutively acting glucosyltransferases synthesizing the major lipids MGlcDAG and DGlcDAG. While the fine details of the molecular mechanisms regulating the synthesis of the two glucolipids have to be worked out, the experiments with the purified MGlcDAG synthase suggest that enzyme regulation may depend on the enzyme proteins themselves, not requiring a complex multiprotein regulatory mechanism (Berg et al. 2001; Wieslander and Rosen 2002).

Energy-yielding pathways

The small genome size of mollicutes precludes their possession of an extensive range of metabolic activities present in other bacterial groups. Demonstrated metabolic activities appear primarily to be associated with energy generation, rather than with the provision of substrates for synthetic pathways. All the mollicutes examined so far have truncated respiratory systems. They lack a complete tricarboxylic acid cycle and have no quinones and cytochromes, ruling out oxidative phosphorylation as an ATP-generating mechanism (Pollack 2002b). Thus, the energy-yielding pathways of mollicutes produce low ATP yields and relatively large quantities of metabolic end-products, depleting host tissues of the specific substrate metabolized in some cases.

Based on their ability to metabolize carbohydrates, the mollicutes are divided into fermentative and nonfermentative organisms. Members of the fermentative group produce acids from carbohydrates, decreasing the pH of the growth medium. While fermentative mycoplasmas may differ in their ability to utilize sugars other than glucose, this property has only a limited taxonomic value. Interestingly, *M. fermentans* isolates from the urogenital tract of AIDS patients were found to use fructose in preference to glucose (Ozcan and Miles 1999). In man, high fructose concentrations relative to glucose are associated only with seminal vesicle secretions. Thus, fructose-utilizing *M. fermentans* strains may be particularly associated with seminal vesicles and their secretions, and be transmitted in semen.

The sequencing projects of the *M. genitalium* and the *M. pneumoniae* genomes (see Genome sequencing section) showed these mycoplasmas to carry all the

enzymes of the Embden–Meyerhof–Parnas pathway, while the second pathway for metabolizing glucose, the pentose phosphate pathway is incomplete. Pyruvate generated by glycolysis can be further metabolized either to lactate by lactate dehydrogenase, or to acetyl-CoA by the pyruvate dehydrogenase pathway. Most of the nonfermentative mollicutes, and some fermentative species as well, possess the arginine dihydrolase pathway. Arginine hydrolysis by this pathway results in the production of ornithine, ATP, CO_2, and ammonia, raising the pH of the culture medium (Razin 1978). The pathway consists of three enzymes: arginine deiminase, ornithine carbamoyl transferase, and carbamate kinase. The degradation of arginine is coupled to equimolar generation of ATP by substrate level phosphorylation. The possible role of this pathway as a sole energy generating source in nonfermentative mollicutes has been frequently questioned (Himmelreich et al. 1996, 1997; Razin 1978). The demonstration of an arginine-ornithine antiport system in *Spiroplasma melliferum* requiring no ATP for arginine import into the cells, supports an energetic advantage in arginine utilization (Shirazi et al. 1995), but the question of whether arginine degradation can serve as a sole, or even a major, energy-generating mechanism remains unanswered.

The arginine dihydrolase pathway can also be found in some fermentative *Spiroplasma* and *Mycoplasma* species (Appendix in Tully and Razin 1996). In this case, when both glucose and arginine are present in the medium, the acids produced by glycolysis would mask the alkalinization caused by the ammonia liberated on arginine degradation, hampering the test for arginine utilization by the simple pH change assay. Yet, as was shown in a ^{13}C-NMR study, the accumulation of lactate and breakdown of arginine by *M. fermentans* were observed in the simultanous presence of both glucose and arginine, suggesting that glucose utilization has little or no effect on deimination of arginine to citrulline (Olson et al. 1993). Furthermore, proteome analysis of *S. melliferum* showed that the arginine dihydrolase enzyme proteins were constitutively also expressed in the presence of glucose (Cordwell et al. 1997a).

Some mycoplasmas, such as *M. agalactiae*, *M. bovigenitalium*, and *M. bovis* metabolize neither sugars nor arginine, but are capable of oxidation of organic acids (lactate, pyruvate) to acetate and CO_2 (Taylor et al. 1994). The contribution of the oxidation of these substrates to energy provision of the above mycoplasmas should be worked out. Another potential energy-yielding mechanism in mollicutes is based on ATP generation from acetyl phosphate and adenosine 5′-diphosphate by acetate kinase, coupled with acetyl phosphate formation from acetyl coenzyme A (acetyl-CoA) by phosphate acetyl transferase; both enzymes are commonly found in fermentative and nonfermentative mollicutes. Acetyl-CoA can be produced by oxidative phosphorylation of pyruvate by mycoplasmas (Razin 1978). The weight to be given to this pathway in energy metabolism of mollicutes has not been critically evaluated.

Energy metabolism of ureaplasmas presents a special case. Neither glycolysis nor arginine dihydrolase-ATP-generating pathways could be detected in these organisms. Ureaplasmas are unique among the mollicutes in possessing a very potent urease. Although protein and gene analysis of the ureaplasmal urease complex has shown it to resemble other prokaryotic ureases in subunit structure and composition, the specific activity of the ureaplasmal urease is much higher, and was estimated to exceed that of jack bean urease by about 100-fold (Blanchard et al. 1988). More importantly, ureaplasmas appear to be unique among prokaryotes in requiring urea for growth (Razin 1978). Thus, the specific urease inhibitor, flurofamide, inhibits ureaplasma growth (Blanchard et al. 1988). The dependence of ureaplasmas on urea for growth has led to the hypothesis that intracellular urea hydrolysis and the resulting intracellular accumulation of ammonia/ammonium ions is coupled to ATP synthesis through a chemiosmotic type of mechanism (Razin 1978). Experimental support for the generation of a transmembrane potential, with resultant ATP synthesis through the ureaplasmal F_0–F_1-type ATPase, first provided by Romano et al. (1980) was later extended and confirmed by Smith et al. (1993). At an external pH of 6.0, the pH optimum for ureaplasma growth in vitro, urea hydrolysis generated an ammonia chemical potential equivalent to almost 80 mV and, simultaneously, an increase in proton electrochemical potential (Δp) of about 24 mV with resultant de novo synthesis of ATP (Smith et al. 1993). When the external pH of the growth medium reaches about 8.1, due to ammonia released from the cells, the intracellular pH rises to 8.6 and urease activity ceases. ATP generation is blocked at this alkaline pH, leading to the abrupt and steep decline of growth, characterizing the ureaplasmal growth curve. Inhibition of the urease by flurofamide abolished both the chemical potential and the increase of Δp, such that ATP synthesis decreased to approximately 5 percent of the normally obtained levels (Smith et al. 1993; Glass et al. 2000). It is worth mentioning at this point that the pH of the urogenital tract is usually on the acid side of neutrality, corresponding to the pH values optimal for ureaplasma growth, maximum increase in Δp, maximum ammonia chemical potential, maximum urease activity, and maximum ATP generation.

Resembling other eubacteria, mollicutes possess an F-type ATPase (Razin 1978). The number and order of genes of the *atp* operon coding for the F_0F_1 ATPase of mollicutes are identical with those of *E. coli* and *Bacillus subtilis*. However, the b subunit (atpF) of the mycoplasmal ATPase was found to carry the characteristic features of a lipoprotein (Pyrowolakis et al. 1998). This feature, unknown for any other eubacterial ATPase, may explain the long known inability to detach the

mycoplasmal ATPase activity from the cell membrane by varying the osmolarity of the medium or by treating the membrane with EDTA (Razin 1978).

Transport

The expectation to find in *M. genitalium* and *M. pneumoniae* a proportionally high number of genes involved in transport of the many essential nutrients required for growth of these organisms has not been substantiated (Fraser et al. 1995; Himmelreich et al. 1996; Paulsen et al. 1998; see Genome sequencing section). This has led to the notion that at least some of the transport systems, such as those for amino acids and oligopeptides, might not be very specific, an assumption for which little experimental evidence is available thus far (Fraser et al. 2000; Pollack 2002a).

Mycoplasmas, lacking a functional TCA cycle, generate ATP as their primary energy source, and consequently have mostly ATP-dependent permeases, while *B. subtilis* generates a proton motive force (pmf) as its primary source of energy and accordingly utilizes mostly pmf-dependent carriers (Paulsen et al. 1998). The ABC transporter systems are involved in import or export of a large variety of substrates, including sugars, peptides, proteins, and toxins. In fact, the ABC transporters were the most frequent class of proteins found in *B. subtilis* (Kunst et al. 1997) and in *E. coli* (Blattner et al. 1997). Generally, bacterial ABC importers have an ATP-binding domain and membrane spanning domains located on separate polypeptides, whereas the ABC exporters may carry these components on the same or on different polypeptides (Blanchard et al. 1996). Putative ABC transporter genes were reported in *M. hyopneumoniae* (Blanchard et al. 1996), in *U. urealyticum(parvum)* (Glass et al. 2000), *M. pulmonis* (Chambaud et al. 2001), and essentially in all the mollicute genomes sequenced so far; *M. pulmonis* showing the highest number, 56, of genes potentially encoding subunits for ABC transporters. The deduced amino acid sequence of these gene products showed significant homology with the ABC transporter proteins, particularly those of the eukaryotic multidrug resistance (MDR) protein family, a finding previously reported for other bacteria (Paulsen et al. 1998).

M. genitalium and *M. pneumoniae* take up amino acids via two amino acid-polyamine choline (APC) transporters, and they probably accumulate peptides and polymers via two distinct ABC-type systems. These four permeases presumably provide the requisite precursors for protein synthesis (Himmelreich et al. 1996; Paulsen et al. 1998). While trials to identify the substrate-binding domain (OppA) of the ABC oligopeptide transport in *M. genitalium* and *M. pneumoniae* failed (Himmelreich et al. 1996), the study by Henrich et al. (1999) has identified an OppA in the homologous ABC transport system in *M. hominis*, functioning in binding peptides of different length that could endow the transporter with a less restrictive substrate specificity.

The highly efficient phosphoenolpyruvate-dependent sugar phosphotransferase transport systems (PTS) have been reported in mollicutes long ago, and some of their components were partially characterized by classical biochemical methodology (Razin 1978). It appears that *M. genitalium* and *M. pneumoniae* deviate a major fraction of their transport capacity to the task of sugar uptake for the purpose of carbon and energy acquisition. Thus, they possess both glucose and fructose phosphotransferase systems, two sugar permeases of the ABC superfamily, and a nonspecific channel protein of the MIP family, probably capable of transporting small, neutral, straight chain molecules, such as urea, glycerol, and various polyols (Paulsen et al. 1998). Interestingly, a defective PTS system lacking component E1 was found in *U. urealyticum (parvum)* possibly explaining the inability of this mycoplasma to utilize sugars (Glass et al. 2000).

GENETICS

Genome structure

The application of pulse-field gel electrophoresis (PFGE) to mycoplasma genome size determinations has provided a much more accurate and labor-saving procedure than the previously used renaturation kinetics method, resulting in a wealth of genome size data (Neimark and Lange 1990). The data show a continuum of genome sizes among mollicutes, ranging from less than 600 kb to over 2200 kb, with overlapping values between mollicute genera. Thus, genome sizes of *Mycoplasma* species range from 580 kb for *M. genitalium* to 1 380 kb for *M. mycoides* subs. *mycoides* LC, while for the helical *Spiroplasma* species genome size ranges from 780 kb for *S. platyhelix* to 2 220 kb for *S. ixodetis* (Table 1). As a general rule, *Acholeplasma* and *Spiroplasma* species, considered phylogenetically as 'early' mollicutes, have larger genome sizes than *Mycoplasma* and *Ureaplasma* species, considered to be phylogenetically more 'recent' mollicutes (see Phylogeny and taxonomy section). The genome size of representative members of 12 major phylogenetic groups of the uncultured phytoplasmas were recently determined (Marcone et al. 1999). Genome size varied between 530 and 1 350 kb, also showing considerable size variation among members of the same phylogenetic group, resembling in this respect the cultured mollicutes. The Bermuda grass white leaf phytoplasma chromosome of 530 kb is not only the smallest mollicute chromosome found to date, but is also the smallest chromosome known for any living cell. Competing with the mollicutes for the title of organisms with the smallest genome are the *Buchnera* species, with a genome size ranging from

450–670 kb (Gil et al. 2002). However, *Buchnera* species are mutualistic intracellular symbionts of aphids, while *M. genitalium* is a self-replicating bacterium independent on other cells for growth. The size of the *Eperythrozoon suis* genome, reclassified now as a mycoplasma (Phylogeny and taxonomy section) is about 750 kb and that of *Haemobartonella felis* reclassified as *Mycoplasma haemofelis*, is about 1 199 kb (Berent and Messick 2003), that is, well within the range of mollicute genomes (Messick et al. 2000).

The mycoplasma genome is characteristically low in G + C content. With very few exceptions, the G + C content of mycoplasma genomes is within the range of 24 to 33 mol% (Appendix in Tully and Razin 1996). The G + C distribution along the genome is uneven. Thus, while the average G + C content of the *M. genitalium* genome is 32 mol%, the G + C content of its rRNA genes is 44 mol%, and of its tRNA genes 52 mol% (Fraser et al. 1995). The *M. pneumoniae* cytadhesin genes, P1 and ORF6, and their repetitive sequences, exhibit a G + C content as high as 56 mol%, while on the other extreme the origin of replication of this mycoplasma has a G + C content of only 26 mol%, compared to 40 mol% of the entire *M. pneumoniae* genome (Himmelreich et al. 1996, 1997). Consequently, many of the mycoplasmal intergenic regions are richer in A + T than the coding regions, reaching values as high as 80–90 mol% (Dybvig and Voelker 1996; Yogev et al. 1991a). The variable G + C content of coding regions within the mycoplasmal genome has phylogenetic relevance, indicating in the case of the rRNA and tRNA genes their highly conserved nature, and in the case of the cytadhesin genes, their possible exogenous origin (see Adhesion to host cells section).

As in other prokaryotes, some of the adenine and cytosine residues in mycoplasmal genomes may be methylated (Dybvig and Voelker 1996; Razin 1985). In many mycoplasmas the adenine residues at the GATC site are methylated, while in others cytosine residues are methylated. Of special interest is the exclusive methylation of the genomic cytosine residues of *S. monobiae* (MQ-1) when they are located 5′ to guanine (CpG), a methylation trait considered unique to eukaryotes (Renbaum et al. 1990).

Extrachromosomal elements

Among the mollicutes, spiroplasmas and acholeplasmas are most frequently infected by a variety of viruses (phages), whereas very few viruses are known to infect *Mycoplasma* species. The characteristics of mollicute viruses have been described and discussed in detail previously (Maniloff 1992; Renaudin 2002). The mollicute phage DNA genomes range in size from 4 to 40 kb, and may be either circular or linear, and single- or double-stranded (Dybvig and Voelker 1996). Of the very few phages infecting *Mycoplasma* species, the most recent phage discovered is the lysogenic phage MAV1, infecting *M. arthritidis* (Voelker and Dybvig 1999). The finding that this phage is associated with highly arthritogenic strains, and that experimental infection of low-virulence *M. arthritidis* strains with this phage increases significantly their arthritogenicity, suggest that MAV1 carries a virulence enhancing factor. Sequencing of the 15.644-bp MAV1 linear double-stranded genome revealed 15 ORFs. The deduced product of one of the genes, designated *vir*, contained a classic prokaryotic lipoprotein signal sequence. If MAV1 encodes in fact a lipoprotein, it may be speculated that this lipoprotein is incorporated into the *M. arthritidis* cell membrane and in this way induces the conversion of the avirulent phenotype into a virulent one (see also Pathogenicity section).

Plasmids were detected in *S. citri*, and in *M. mycoides* subsp. *mycoides* (Dybvig and Voelker 1996). Extrachromosomal DNA molecules, most prevalent in phytoplasmas of various phylogenetic clades have been postulated to represent plasmids, as no virus particles could be observed by electron microscopy (Rekab et al. 1999). The almost universal occurrence of plasmids in phytoplasmas suggests a function for these molecules. The possibility that phytoplasma plasmids may encode genes associated with pathogenicity (Nishigawa et al. 2002) has been raised, but evidence to support this notion is still missing. The potential of the mollicute phages and plasmids to serve as cloning and shuttle vectors has been a major reason for interest in these elements (see Gene transfer section).

Genome sequencing and gene annotation

Mycoplasmas, carrying the smallest genomes of self-replicating cells, were among the first microorganisms selected for the genome sequencing projects. The complete sequence of the genome of *M. genitalium* was second to that of the *Haemophilus influenzae* genome to be reported (Fleischmann et al. 1995; Fraser et al. 1995). The remarkable power and cost-effectiveness of the new genome sequencing technology have already resulted in the elucidation of the complete genome sequences (as of January 2003) of over 90 eubacteria and archeons (see www.tigr.org/tdb/mdb/). Included among these are the mollicutes *U. urealyticum* (*U. parvum*) (Glass et al. 2000), *M. pulmonis* (Chambaud et al. 2001), and *M. penetrans* (Sasaki et al. 2002). The complete sequencing of the *M. gallisepticum* genome has already been accomplished (Papazisi et al. 2003). The genomes of *M. hyopneumoniae*, *M. mycoides* subsp. *mycoides*, and *S. citri* are at advanced or final stages of sequencing. A large part of the *S. kunkelii* genome has been sequenced and annotated (Bai and Hogenhout 2002).

The voluminous amount of genetic data provided by the genomic projects has opened the way for

'comparative genomics' by which the total genomic complements of organisms could be compared. This provides an opportunity to explore the functional content of genomes and evolutionary relationships between organisms at a new qualitative level. Typically, about 40–60 percent of the genes of a newly sequenced bacterial genome display detectable similarity to protein sequences whose function is at least tentatively known. Gene density is consistent across many bacterial species, with about one gene per kilobase (Fraser et al. 2000). A detailed comparative genomic analysis of *M. genitalium* and its close relative *M. pneumoniae*, compared to that of *H. influenzae* and other eubacteria was presented in Razin et al. (1998). Table 3 summarizes some of the gross properties of the mollicute genomes sequenced so far, in comparison with the *Bacillus subtilis* genome.

Examination of the mycoplasmal genomic data points out the biochemical pathways where economization in genes took place during their reductive evolution, and helps us define the genes which are apparently essential for life of a minimal self-replicating cell. In fact, the definition of the minimal gene set required for life has become a most attractive research subject, applying *M. genitalium* as a prime candidate for this purpose (Hutchison and Montague 2002; Koonin 2000; Razin et al. 1998). Moreover, Hutchison et al. (1999) have promoted the idea of constructing an artificial life form based on the genes found essential for *M. genitalium* survival following global transposon mutagenesis. The essential genes were defined, in part, by the absence of viable mutants containing a transposon insertion within a given coding region. Hutchison et al. identified 243 *M. genitalium* genes in this way whose functions are not essential for cell viability. From this analysis (coupled with statistical and computational analysis) the authors concluded that 265–350 of the 517 genes in *M. genitalium* are essential for its life under laboratory growth conditions, that is, in the presence of a full complement of essential nutrients and in the absence of environmental stress. Recent announcements in public communication media and in *Nature* (Check 2002) and in *Science* (Zimmer 2003) indicate that Venter, Smith and Hutchison have already initiated a most ambitious endeavor directed at the synthesis of an artificial minimal cell. Their idea is to synthesize first an artificial genome, based on the genes found essential for life of *M. genitalium*, and introduce this synthetic genome into *M. genitalium* cells from which the natural genome was removed. Whether the synthetic genome will 'hijack' the cellular machinery of the genome-depleted host cell is, of course, a great mystery. A most interesting article relevant to the issue of the 'minimal cell' concept is that of Kobayashi et al. (2003). By systematic inactivation of *B. subtilis* genes, they could show that only 271 of the 4 112 genes of this bacterium (Table 3) appear essential for its survival and growth under optimal conditions, again demonstrating how little genetic information is theoretically needed for the assembly of a minimal cell.

Comparative genomics

Genomic analysis of *M. genitalium* and *M. pneumoniae* has revealed the scarcity of genes involved in biosynthetic pathways (for detailed discussion see Dandekar et al. 2002 and Razin et al. 1998). The two mycoplasmas have apparently lost all the genes involved in amino acid biosynthesis during their reductive evolution, as well as most of the genes involved in cofactor (vitamin) biosynthesis, so that to cultivate these mycoplasmas in vitro the medium has to be supplemented with the essential amino acids and vitamins. Very significant savings in genetic information have resulted through the loss of the cell wall during mycoplasma evolution. Significant gene saving is also pronounced in lipid metabolism. Most mycoplasmas cannot synthesize any fatty acid and depend, therefore, on the host for their supply (see Membrane lipids section). Being deficient in the ability to regulate membrane fluidity by preferential fatty acid biosynthesis, most mycoplasmas overcome this deficiency by incorporating large quantities of exogenous cholesterol into their membrane. Cholesterol serves as a very effective buffer of membrane fluidity (Razin 1978). Our early studies on mycoplasma nutrition revealed their requirement for the nucleic acid precursors, purines, and pyrimidines. These may be provided by RNA and DNA degraded by the potent mycoplasmal nucleases (Razin 1978). The present genetic data provide an explanation for these observations by

Table 3 *Gross properties of sequenced mollicute and* Bacillus subtilis *genomes*[a]

Property	*U. urealyticum*	*M. pneumoniae*	*M. genitalium*	*M. pulmonis*	*M. penetrans*	*B. subtilis*
No. of base pairs	751 719	816 394	580 074	963 879	1 358 633	4 214 814

No. of ORFs with no functional prediction or database match	295	230	152	204	453	1 722

a) Based on data of Glass et al. (2000), Himmelreich et al. (1996, 1997), Dandekar et al. (2000), Fraser et al. (1995), Chambaud et al. (2001), Sasaki et al. (2002), and Kunst et al. (1997).

revealing the scarcity in mycoplasmas of genes, and consequently of enzymes, responsible for purine and pyrimidine synthesis while genes for salvage pathways utilizing purines and pyrimidines for the synthesis of ribonucleotides and their conversion to deoxyribonucleotides have been detected in mycoplasmas (Fraser et al., 1995; Himmelreich et al., 1996; Tham et al., 1993). It should be emphasized that the picture of extreme reduction in biosynthetic genes, described above for *M. genitalium* and *M. pneumoniae*, is less pronounced on analysis of larger mollicute genomes. Thus, the 1 600 kb genome of *S. kunkelii* carries genes for de novo synthesis of several amino acids and nucleosides, as well as regulatory factors not found in *M. genitalium* and *M. pneumoniae* (Bai and Hogenhout 2002).

The number of genes involved in cellular processes, such as the *fts* genes associated with cell division, heat shock proteins, and genes for chaperone functioning in protein secretion, is definitely smaller in the mycoplasmas as compared to other eubacteria. However, the major chaperone families HSP70 (DnaK) HSP60 (GroEL), and associated components (e.g. DnaJ, GroES, and GrpE) as well as the folding isomerase and the trigger factor are present in *M. pneumoniae* and *M. genitalium*. In essence, all the constituents of a basic protein folding machinery are present (Bang et al. 2000). Yet, the genes for the chaperonins GroES and GroEL were not detected in *U. urealyticum (parvum)* so that different mollicute systems may vary in detail (Glass et al. 2000). The protein secretion system in *M. pneumoniae* is much less complex than in *E. coli*. The channel-forming proteins SecG, SecF, SecE, SecD were not identified in the mycoplasma, leaving only SecA, SecB, SecY, trigger factor, bacterial signal recognition particle, and FtszY as the components of a simplified translocon in *M. pneumoniae* (Himmelreich et al. 1996; Edman et al. 1999; Dandekar et al. 2000).

Many of the regulatory system genes found in other bacteria, such as the two-component signal transduction systems consisting of a sensor and response regulator, were not detected in *M. genitalium* and *M. pneumoniae* as well as the recognizable vestiges of the histidine protein kinases or their target response regulators. Generally, a rough correlation can be observed between genome size and the number of putative protein kinases and protein phosphatases. Thus, while *M. genitalium* carries a single potential protein kinase, *Synechocystis* carries nine potential protein kinases and ten potential protein phosphatases (Shi et al. 1998). *Synechocystis*, with its ability to survive at the barest of environmental resources, light and air, presumably has developed and maintained a more extensive cellular sensory, command, and control apparatus to support its lifestyle than organisms like *M. genitalium* and *M. pneumoniae* that specialized to efficiently exploit more monotonous environmental niches (Shi et al. 1998). The *M. penetrans* genome differs from the other mycoplasma genomes sequenced so far (Table 3) by carrying the genes for a predicted two-component signal system (Sasaki et al. 2002). The absence of identifiable transcription factors from *M. genitalium* is most striking. While *E. coli* has 55 known transcriptional activators and 58 repressors, *M. genitalium*, apart from *nusA* and *nusG*, contains only a single transcription elongation factor (Ouzounis et al. 1996) and the *M. pulmonis* genome was found to carry only two transcription regulation factors (Chambaud et al. 2001). Relevant to this issue is the observation that FruR, the product of the *S. citri* gene *fruR*, acts as an activator of the fructose operon transcription in the spiroplasma. This appears to be the first mollicute operon for which regulation of transcription is documented (Gaurivaud et al., 2000c).

The mollicute genomes sequenced so far are deficient in genes coding for components of intermediary and energy metabolism. Thus, *M. genitalium* and *M. pneumoniae* depend primarily on glycolysis as a means for synthesizing ATP. Genes that encode the components of the pyruvate dehydrogenase complex, phosphotransacetylase, and acetate kinase were also detected, as well as a deficient pentose phosphate pathway (Fraser et al. 1995; Himmelreich et al. 1996). Most striking is the lack of many energy-yielding systems from the mycoplasmas. No tricarboxylic acid cycle, and no quinones nor cytochromes were found in any of the mycoplasmas tested (see Energy-yielding pathways and Transport sections). In terms of reductive evolution strategy, mollicutes may have concentrated two different functions in a single gene during genome size reduction, as evidenced by the malate dehydrogenase (MDH) and lactate dehydrogenase (LDH) example (Cordwell et al. 1997b), where the gene putatively assigned to lactate dehydrogenase in *M. genitalium* and *M. pneumoniae* fulfils both LDH and MDH functions. Along this line, a lipoprotein of *M. hominis* functioning as a cytadhesin, was recently shown to also function as the substrate-binding domain OppA of an oligopeptide permease of *M. hominis* (Henrich et al. 1999). The inability to detect in the mollicute genomes sequenced so far the genes for nucleoside-diphosphate reductase and nucleoside diphosphate kinase was surprising, as these are considered indispensable, ubiquitous, and highly conserved genes, playing a key role in the synthesis of nucleotide triphosphates. A way out of this problem was proposed by Pollack et al. (2002) suggesting that glycolytic kinases are capable of using a variety of purine and pyrimidine di- and trinucleosides as phosphate donors or acceptors rather than ATP and in this way supply the required di- and trinucleotides.

Being dependent on the exogeous supply of many nutrients would predict the need of mycoplasmas for many transport systems. However, the percentage of genes devoted to transport in *M. pneumoniae* and *M. genitalium* is no higher than in *H. influenzae*, while their

absolute number is much lower. The relative small number of transport genes in the two mycoplasmas is even more striking when compared to the 281 transport and binding proteins annotated in *E. coli* K-12 (Blattner et al. 1997) and almost 400 in *B. subtilis* (Kunst et al. 1997). The apparent low substrate specificity of some of the mycoplasmal transport systems, such as those for amino acids (Himmelreich et al. 1996) may contribute to the significant gene saving observed in this category (see Transport section).

The essential role of the basic processes of DNA replication, transcription, and translation, leads us to expect that saving of genes in these categories will be more restricted as compared to metabolic processes. In fact, while the absolute number of genes involved in DNA replication in the mycoplasmas is still much smaller than in *Haemophilus*, the percentage of genes devoted to DNA replication and degradation in *M. genitalium* and *M. pneumoniae* is higher than in *H. influenzae*, pointing to the essential biological role of these genes, so that evolutionary deletion of genes in this category had to be limited. Obviously, it is of interest to define the genes missing from the mycoplasmas, as these are apparently of secondary importance. For example, while the estimated number of genes functioning in DNA repair in *E. coli* is estimated to be about 100 (Blattner et al. 1997), only 13 of the genes in this category were found by Himmelreich et al. (1996) in *M. pneumoniae*. We may assume that those genes detected in the mycoplasmas, including the uracil DNA glycosylase, the ABC exinucleases, and *recA*, must represent the genes really essential for DNA repair (see DNA replication and repair section).

The percentage of genes devoted to transcription is also higher in the mycoplasmas than in other eubacteria though their absolute number is definitely smaller in the mycoplasma. Included in this category are the genes for the RNA polymerase subunits, which are basically similar in mycoplasma and the other eubacteria (see Transcription section). The translation and protein synthesis machinery apparently constitutes the most conserved system in eubacteria, indicating that it represents a very efficient and successful evolutionary development. Thus, in composition, the mycoplasmal translation components very much resemble those of other eubacteria. A marked difference can, nevertheless, be observed in the small copy number of the rRNA and tRNA genes (Table 4 and Ribosomes, ribosomal RNAs and Transfer RNA sections). The mycoplasmas thus appear to possess the minimum machinery needed for protein synthesis. Consequently, protein synthesis and cell replication in mycoplasmas is much slower than in *E. coli*; the velocity of the DNA replication fork was about ten times slower in *M. capricolum* than in *E. coli* (Seto and Miyata 1998). Yet, mycoplasmas appear to grow well in the protective and constant environment of their host and a slow replication rate cannot really be considered as a deficiency of a parasite that can only lose by killing its host. In fact, mycoplasma infections are usually rather mild, and chronic in nature (see Pathogenicity section).

There can be little doubt that the considerable economization in genes depends primarily on the obligate parasitic lifestyle of mycoplasmas. Some genomic price has to be paid for parasitism; that is, mycoplasma cells must possess surface components enabling their attachment to the host cells. In some cases, including *M. genitalium* and *M. pneumoniae*, the mycoplasmas developed special attachment organelles (Cellular morphology and cytoskeletal elements section). Obviously, a significant number of genes is involved in construction of such organelles. Some of these genes have already been identified and characterized, but some have not, and are apparently included in that part of the mycoplasmal coding regions or genes unidentified as yet (see Adhesion to host cells section).

Proteome and transcriptome analyses and bioinformatics

Many ORFs that are identified in the genomic sequence of a particular organism have structurally and function-

ally well-characterized homologs in other organisms and it is possible, therefore, to assign the putative protein structure and function through bioinformatics by similarity searches in protein databases. However, for a large fraction of ORFs neither structure nor function can be assigned by sequence comparisons.

Experimental identification and confirmation of the proposed gene products at the cellular level has become complementary to identification by sequence comparison. Gene expression can be studied either at the level of transcription or at the level of translation. When these analyses are carried out on intact cells the term 'transcriptome' is defined as the sum of all transcripts derived from a genome, while the term 'proteome' refers to the expressed total protein complement of a genome.

Transcriptome analysis uses microarray technology allowing the analysis of gene expression at the transcription levels of thousands of genes simultaneously (Weiner et al. 2002). For this purpose total RNA is isolated from the mycoplasma grown under defined laboratory conditions. The RNA is transcribed into a single-stranded complementary DNA and is labeled with ^{33}P. Specific probes are synthesized for all proposed ORFs by PCR, and the probes are immobilized on nylon membranes, and tested for cross-hybridization with the labeled cDNA. This technique was used to analyze gene expression in *M. pneumoniae* grown under various conditions, such as heat shock, oxidative stress, and growth in the presence of different antibiotics (Weiner et al. 2000, 2002). Of the 688 proposed *M. pneumoniae* genes about 600 were transcribed, but transcription of many genes was temperature dependent and therefore regulated, while numerous genes were constitutively expressed at all temperatures. Interestingly, a substantial proportion of genes with high transcription signals had no known function. Yet, their high expression level suggests that they code for important products (Weiner et al. 2002).

Proteome analysis involves two-dimensional (2D) gel electrophoresis for the separation of proteins according to isoelectric point (pI) and molecular mass, knowledge of the sequences of all cell proteins and mass spectrometry for the characterization of individual proteins. The combination of peptide mass fingerprinting and peptide fragmentation which matches the masses of in-gel proteolytically generated peptides against theoretically digested proteins from the database, has proven to be very effective and reliable (Regula et al. 2000; Weiner et al. 2002; Ueberle et al. 2002).

Mycoplasmas are particularly suitable for proteome analysis, as a high percentage of their proteins can be visualized by 2D-gel electrophoresis, analyzed, and identified. Moreover, the highly conserved nature of a large part of mycoplasmal proteins facilitates their identification. The major limitations of the proteome approach are: (1) Not all cell proteins are expressed at a given time. Thus, it is improbable that an entire proteome can be visualized under a specific set of experimental conditions. (2) The detection threshold of 2D-PAGE is a limiting factor, as a low copy number of protein molecules may not be detected. (3) Proteins with an isoelectric point higher than 11 cannot be separated well in the first dimension of immobilized pH gradients, as well as proteins with five or more transmembrane segments. (4) Presently, proteome analysis is only useful for identifying proteins for which the DNA sequence of their genes is available. (5) Co- and posttranslational modification of proteins may increase the number of protein spots per gene (Ueberle et al. 2002).

The pioneering work on mollicute proteome analysis was carried out by Humphery-Smith and colleagues on *Spiroplasma melliferum* (Cordwell et al. 1997a) and on *M. genitalium* (Wasinger et al. 1995) at a time when complete genome sequences were not available and the sensitivity and accuracy of mass spectrometry methods were inferior to those of today. In a more recent study Wasinger et al. (2000) resolved 427 protein spots in proteome analysis of exponentially-grown *M. genitalium* cells. Of the 201 proteins of sufficient abundance, 158 could be identified by peptide mass fingerprinting. A reduction of 42 percent in protein spots was noticed in post-exponentially grown cells. On the whole, only about one-third of the proteins in the predicted *M. genitalium* proteome could be identified by them. Proteome analysis of *M. pneumoniae* by Regula et al. (2000) characterized about 350 protein spots. It was possible to assign these 350 proteins to 224 genes. Clearly, the *M. pneumoniae* proteome map is still far from being as complete as that of *M. genitalium*. Ueberle et al. (2002) concluded that due to the technical problems discussed above, a complete proteome analysis based on the separation of cell proteins by 2D-gel electrophoresis cannot be achieved at the present, even for simple organisms like *M. genitalium* and *M. pneumoniae*.

DNA replication and repair

The recent mycoplasma genome sequencing projects, as well as the study of Barnes et al. (1994) on *M. pulmonis* DNA polymerases, have considerably clarified the nature of the mycoplasmal DNA polymerases. It appears that the mycoplasmas carry the central enzyme for DNA replication – the DNA polymerase III holoenzyme (Pol III) that has the essential characteristics of the eubacterial gram-positive Pol III. Although the genes responsible for building the major subunits of the holoenzyme, such as the α (*dnaE* or *polC*) and β subunits (*dnaN*) were detected, several other genes responsible for other subunits were missing from the *M. genitalium* and *M. pneumoniae* genomic analysis (Fraser et al. 1995; Himmelreich et al. 1996) indicating a simplified DNA replication complex in the mycoplasmas compared to that of *E. coli* or *H. influenzae*. Yet, most impor-

tantly, the mycoplasmal Pol III α-subunit (about 1 400 amino acids) included the motif for 3′–5′ exonuclease activity typical for Pol C of gram-positive bacteria (Barnes et al. 1994; Himmelreich et al. 1996; Kunst et al. 1997), providing an answer to the question of the way DNA proofreading is done in mycoplasmas.

Barnes et al. (1994) presented experimental evidence for a second enzyme with DNA polymerase activity in *M. pulmonis*. This correlates with sequence data for *M. genitalium* and *M. pneumoniae* indicating that at least these three *Mycoplasma* species carry two DNA polymerase genes, one coding for the larger protein (about 166 kDa) with a 3′–5′ exonuclease activity, with high sequence similarity to the *B. subtilis* polymerase III, and the other gene coding for a Pol III homolog (about 100 kDa) resembling more the *polC* gene from *E. coli*, lacking a 3′–5′ exonuclease domain. This smaller enzyme may correspond to the DNA polymerases lacking exonuclease activity isolated earlier from *M. orale* and *M. hyorhinis* (Razin 1985). The picture appears different for the recently sequenced genome of *Spiroplasma kunkelii* where its larger genome carries a *polA* gene that may encode the full length DNA polymerase I protein, including the proofreading and Klenow domains, resembling in this respect *Streptococcus pneumoniae* (Bai and Hogenhout 2002).

Topoisomerases (topos) catalyze the interconversions of topological isomers of DNA molecules, fulfilling an essential role in DNA replication, transcription, recombination, and repair. The mycoplasmal DNA topos, characterized so far, are the DNA gyrase and topoisomerase IV, both belonging to type II topos. Both mycoplasmal enzymes resemble their eubacterial counterparts in having a tetrameric structure composed of two subunits: A and B in the case of DNA gyrase, and the products of *parC* and *parE* genes in the case of topoisomerase IV (Bebear et al. 1998; Ladefoged and Christiansen 1994). Interest in the molecular characterization of mycoplasmal topoisomerases has been boosted by the fact that these enzymes are the targets of fluoroquinolones, among the most effective antimycoplasmal drugs (Bebear and Bebear, 2002; Kenny et al., 1999; Reinhardt et al., 2002).

The three genes coding for the ABC excinucleases are present in *M. genitalium*, *M. pneumoniae*, and *M. capricolum* so that together with Pol I, helicase II, and ligase, should provide the mechanism for repair of UV damage, such as crosslinking. While dark reactivation of UV damage (excision repair) operates in the above mycoplasmas, photoreactivation may be missing as the photolyase (*phr*) gene could not be identified in *M. genitalium* and *M. pneumoniae*. The RecA protein plays a central role in recombination repair, homologous recombination, and initiation of the SOS response. The *recA* gene has been found essentially in all the mollicutes analyzed so far (Zou and Dybvig 2002). Surprisingly, *S. citri* R8A2 was found to lack a significant portion of the N-terminus of RecA (Marais et al. 1996) affecting its function. However, truncation of RecA is not a characteristic of other *Spiroplasma* species, such as *S. melliferum* (Melcher and Fletcher 1999; Cordwell et al. 1997a). Not surprisingly, searching of DNA repair systems in mollicutes has been associated with the high mutation rates and high tempo of evolution in Mollicutes (Rocha and Blanchard 2002). For an in-depth treatment of the issue of DNA replication and repair in mycoplasmas, the reader is referred to Zou and Dybvig (2002).

Transcription and translation

The DNA-dependent RNA polymerase of mollicutes resembles in subunit structure that of other eubacteria. Thus, the core RNA polymerase of *M. genitalium* (Fraser et al. 1995) and *M. pneumoniae* (Himmelreich et al. 1996) is coded by the conserved genes *rpoA* (α subunit), *rpoB* (β subunit), and *rpoC* (β′ subunit). One of the peculiar properties of mollicutes is their resistance to the antibiotics rifamycin and streptolydigin. Cloning and sequencing of the *rpoB* gene from *S. citri* (Gaurivaud et al. 1996) and *M. gallisepticum* (Skamrov et al. 1996) suggest that minor differences in amino acid sequences in the β-subunit Rif region, the region responsible for rifamycin binding, may confer rifamycin resistance.

Modulation of promoter selectivity of RNA polymerase by replacement of the sigma subunits is an efficient way to alter the global pattern of gene expression in response to changes in environmental conditions. Thus, the *E. coli* genome carries at least six sigma factors, and that of *B. subtilis*, 18 (Kunst et al. 1997). The presence of only one sigma factor in the mycoplasmas (Himmelreich et al. 1996) suggests that the response to external stimuli in these organisms is not controlled by the level of expression of alternative sigma factors. Mycoplasmas have conserved the heat shock response, and heat shock proteins, resembling the eubacterial DnaK (HSP70) and GroEL proteins, have been identified in several mollicutes. The *M. genitalium* and *M. pneumoniae* genomes carry genes for seven heat shock proteins (Fraser et al. 1995; Himmelreich et al. 1996). It has been said that the lack of alternative sigma factors from mycoplasmas, two-component signal transduction systems, or other means of gene regulation common to prototypical walled bacteria is almost as striking as their absence of a cell wall.

TRANSCRIPTION SIGNALS

The mycoplasmal transcription signals generally resemble the classical eubacterial ones. The mycoplasmal-10 (Pribnow box) and to a much lesser extent the -35 regions resemble the eubacterial promoter concensus sequences recognized by the RNA polymerase holoenzyme (Weiner et al. 2000). A concensus

Shine–Dalgarno (SD) sequence could also be identified upstream of the initiation codon (Dybvig and Voelker 1996) though in many cases the SD sequence could not be identified, indicating that signals other than the SD sequence may function as a ribosomal binding site for some mollicute genes. Termination of transcription in mollicutes appears to be independent of the termination factor Rho, as its gene could not be detected in the mycoplasmal genomes analyzed thus far.

RIBOSOMES AND RIBOSOMAL RNAS

The translation machinery of mycoplasmas is rather comprehensive. In *M. pneumoniae* and *M. genitalium* it comprises of 99 proposed genes, constituting about 15–20 percent of the genome's ORFs. The mycoplasmal ribosomes are typically prokaryotic in size, shape, and composition (Razin 1985). The *M. pneumoniae* ribosomal protein genes are organized in operons, retaining some of the gene order found in the *E. coli* and *B. subtilis* genomes. Of the 50 ribosomal proteins found in *E. coli* only the gene for protein S1 could not be detected in *M. genitalium* and *M. pneumoniae*, resembling in this respect a number of gram-positive bacteria, including *Bacillus* (Fraser et al. 1995; Himmelreich et al. 1996). The highly conserved nature of the ribosomal protein genes has also found its use in establishing mollicute phylogeny (see Phylogeny and taxonomy section).

Organization of the mollicute rRNA genes generally follows the characteristic eubacterial order: 16S–23S–5S, functioning as an operon (Razin 1985). Some exceptions to the above classical rRNA gene organization have been reported (Razin et al. 1998; Chambaud et al. 2001). Mollicute genomes carry only one or two rRNA gene sets (Table 4), whereas *Clostridium ramosum* and *Clostridium innocuum*, phylogenetically closest to mollicutes, have four and five sets of rRNA genes, respectively (Bove 1993). Interestingly, phytoplasmas carry two rRNA gene sets (Ho et al. 2001), resembling in this respect their phylogenetic relatives, the acholeplasmas (see Phylogeny and taxonomy section).

TRANSFER RNAS

The number of tRNA genes in mollicutes is kept to a minimum, with very few gene duplicates (Table 4). The set of 29 tRNA genes identified in the *M. pulmonis* genome represents the smallest set of tRNA genes among the sequenced genomes (Chambaud et al. 2001). Accordingly, the number of anticodons in the mycoplasmas is not much higher than in mitochondria and is close to the essential minimum for translation of all the amino acid codons by wobbling (Muto and Ushida 2002).

CODON USAGE

Most mollicutes have genomes with a very low G + C content (Table 1), the outcome of an AT-biased directional mutation pressure (A–T pressure) during their evolution (Muto and Ushida 2002). This has resulted in codon usage favoring synonymous codons with A and T, in particular in the wobble (3′) position. Codon bias in the AT-rich mycoplasmas is not limited to the third nucleotide position, and is evident also in the first and second positions. Mycoplasmas have fewer GGN, CCN, GCN, and CGN codons. Another apparent outcome of codon reassignment under strong A–T pressure is the reassignment in most mollicutes of UGA from a stop codon to a tryptophan codon, a feature found in mitochondria (Osawa et al. 1992). As can be seen in Table 4, not all mollicutes share this property. The phylogenetically early acholeplasmas and phytoplasmas (see Phylogeny and taxonomy section) use the conventional UGG codon for tryptophan, carrying $tRNA^{Trp}$(CCA) and retaining UGA as a stop codon. As a consequence of using UGA as a tryptophan codon, it is difficult to express cloned mollicute genes in *E. coli*. Since *E. coli* regards UGA as a stop codon, translation of a mycoplasmal message in *E. coli* will stop where originally there should be tryptophan, so that mycoplasmal proteins expressed in *E. coli* may be truncated. One way to overcome this difficulty is by using an *E. coli* opal suppressor strain for expression (Renbaum et al. 1990) though efficiency of expression falls considerably with increasing numbers of UGAs in the mycoplasmal message. Another way is to employ *Bacillus subtilis* that carries a tRNA which reads the UGA termination codon as tryptophan (Kannan and Baseman 2000).

The elongation factor genes, *fus*, *efp*, *tsf*, and *tuf*, were identified in the *M. genitalium* and *M. pneumoniae* genomes (Fraser et al. 1995; Himmelreich et al. 1996). Of these, the *tuf* gene, encoding the elongation factor EF-Tu that mediates attachment of amino acyl-tRNAs to the ribosome, has attracted most attention. It has been one of the first mollicute genes to be cloned, sequenced, and expressed in *E. coli* (Yogev et al. 1990). Being a highly conserved housekeeping gene found in all mollicutes examined so far, it has been used as an effective genetic probe in taxonomy and phylogeny of mollicutes (see Phylogeny and taxonomy section).

Gene transfer

The lack of a cell wall in mollicutes would be expected to facilitate the introduction of exogenous DNA into the cells. In fact, conjugative transposition of transposon Tn*916* from *Streptococcus (Enterococcus) faecalis* to *M. hominis* (Roberts and Kenny 1987) and to *M. gallisepticum* (Ruffin et al. 2000) by a spontaneous mating process probably involves transient fusion of the cell membranes at the zone of contact. However, DNA transfer efficiency in these cases was rather low. Increased transformation and transfection efficiencies have been achieved either in the presence of polyethylene glycol (PEG) or by application of the electroporation procedure. It appears that the method of choice

depends on the mollicute species, and on the particular DNA to be transferred (Dybvig and Voelker 1996).

Genetic studies in mollicutes have also been hampered by the paucity of selectable markers (Dybvig and Voelker 1996). Most studies on gene transfer in mollicutes have used as selectable markers the *tetM* tetracycline-resistance determinant found on *Tn916*, or the gentamycin-resistance determinant of *Tn4001*. The *tetM* gene is preferable as a marker, since mollicutes in general are sensitive to tetracycline, while not all mollicutes are sensitive to gentamycin (Dybvig and Voelker 1996). Thus, transposon Tn4001 containing the *tetM* gene constructed by Dybvig et al. (2000) was found effective as a broad host-range vector, as indicated by the successful expression of a lacZ fusion gene in both *M. pulmonis* and *M. arthritidis*.

Gene function can only be ascertained by mutational analysis. The recent deluge of information on putatively identified mycoplasmal genes, based on sequence analysis (see Genome sequencing and gene annotation section), has emphasized the need for complementation of these predictions by mutational analysis. Having efficient transformation procedures at hand, major efforts have been directed at developing cloning and shuttle vectors for mollicutes (reviewed by Renaudin 2002). Transfection experiments with the replicative form (RF) of the *S. citri* virus SpV1, carrying as an insert a segment of the gene coding for the P1 adhesin of *M. pneumoniae* (G-fragment) resulted in the expression of the fragment in the spiroplasma. In this case, the presence of seven UGA codons in the G-fragment insert did not interfere with expression, as *S. citri* can read UGA as tryptophan. Yet, the SpV1-RF/*S. citri* cloning system was deficient as it suffered from the rapid loss of the cloned DNA insert. The loss of the insert was suggested to be the result of illegitimate and homologous recombination (Marais et al. 1993). An improved type of a cloning vector for *S. citri* was subsequently constructed by combining the *oriC* of *S. citri* with *tetM* and a colE1-derived *E. coli* replicon. The artificial recombinant plasmid, named pBOT1, was able to replicate in *S. citri* and then integrate into the spiroplasmal chromosome, being stably maintained there (Renaudin 2002). The pBOT1-derived, recombinant plasmids carrying heterologous DNA inserts were effective as shuttle vectors and, for example, restored fructose utilization in a mutant with a defective fructose operon (Gaurivaud et al. 2000a).

TRANSPOSITION

The first successful transformation of *M. pulmonis* and *A. laidlawii* to antibiotic resistance was achieved by a plasmid, pAM120, harboring the streptococcal transposon Tn916 which contains the tetracycline resistance determinant *tetM* (Dybvig and Cassell 1987). The transposon was excised from the plasmid and integrated into the mycoplasmal chromosome at random sites, rendering the mycoplasmas resistant to tetracycline. Since then, a variety of mollicute species were shown to be transformed to tetracycline resistance by *Tn916* or *Tn1545*, or to gentamycin resistance, using the staphylococcal conjugative transposon *Tn4001*, which contains a gentamycin resistance determinant (Foissac et al., 1997; Voelker and Dybvig 1996).

Transposon mutagenesis has already been applied, rather effectively, to generate mutants of *M. pneumoniae* and *M. genitalium* deficient in cytadherence (Krause et al. 1997) and of *S. citri* mutants deficient in motility and pathogenicity to plants (Foissac et al. 1997; Jacob et al. 1997). Characterization of these mutants has already contributed significantly to the identification of genes and their protein products, associated with the mycoplasmal cytoskeleton and cytadherence (see Adhesion to host cells section), spiroplasmal motility (see Cellular morphology and cytoskeletal elements section) and pathogenicity (see Pathogenicity section). There is no doubt that transposon mutagenesis will continue to be a most useful tool in mollicute genetic studies.

While transposon mutagenesis is either random or directed to specific hot spots in the mycoplasmal genome, Dhandayuthapani et al. (1999) have introduced a technology enabling the targeting of mutagenesis to specific genes or operons. The technique is based on creation and delivery of disruption constructs acting by homologous recombination. The constructed plasmids contain the targeted gene and a gentamycin resistance gene. Electroporation of the disruption plasmid, carrying part of the *mg218 M. genitalium* gene, into wild-type hemagglutination-positive *M. genitalium* permitted the isolation of hemagglutination-negative mutants, resulting apparently from homologous recombination at the mg218 locus by single- or double-crossover events. In this way the role of the mg218 protein product in *M. genitalium* adherence could be demonstrated.

RESTRICTION AND MODIFICATION

Restriction and modification of DNA allow a bacterium to distinguish between its own DNA and any 'foreign' DNA which lacks the characteristic host modification pattern. This difference renders an invading foreign DNA susceptible to attack by restriction enzymes that recognize the absence of methyl groups at the appropriate sites. Hence, these systems may pose a serious barrier to gene transfer. Restriction and modification systems in mollicutes have been reviewed by Sitaraman and Dybvig (2002). Generally, the restriction-modification systems characterized in mollicutes in the past were defined as type II restriction-modification (R-M) systems, in which the endonuclease is separate from the methylase. More recently, *M. pulmonis* was found to possess a more complex type I R-M system, built of the

S, M, and R subunits. These subunits form a holoenzyme which performs both the endonuclease and DNA methylase activities (Dybvig et al. 1998).

CHROMOSOMAL REARRANGEMENTS

The mollicute chromosome is a genetically dynamic structure undergoing frequent rearrangements, insertions, deletions, and inversion of genes, or entire genomic segments. The mollicute genome may carry repetitive elements of various types, such as insertion-like sequences, integrated viral or plasmid genomic segments, or repetitive elements of endogenous origin, being constituted of segments of mycoplasmal genes, as well as recombinases recently identified in mycoplasma genomes (Flitman-Tene et al. 2003; Glew et al. 2002; Sitaraman et al. 2002). These are the elements which facilitate, through homologous recombination, chromosomal rearrangements, as well as loss of genomic material by deletion of intervening sequences during recombination, a process presumably taking place during the reductive evolution of mollicutes (Rocha and Blanchard 2002). The various types and mechanisms of chromosomal gene rearrangements in mycoplasmas have recently been extensively reviewed by Sitaraman and Dybvig (2002). Chromosomal rearrangements that play a crucial role in antigenic variation are discussed in the section on Antigenic variation.

INSERTION-LIKE ELEMENTS

Repetitive elements resembling the large IS*3* family of bacterial insertion sequences appear to be rather prevalent in mollicutes (Razin et al. 1998). However, of these, only IS*1138* was shown to actively transpose in *M. pulmonis* (Bhugra and Dybvig 1993), while all the other elements that failed to show transposition within the mycoplasma chromosome are usually referred to as insertion (IS)-like elements. The *M. pulmonis* IS*1138* is the only mycoplasmal IS element shown to transpose in the *M. pulmonis* chromosome at high frequency. The predicted amino acids encoded by the major IS*1138* ORF share significant similarity with the transposases of the IS*3* family, suggesting that IS*1138* has a potential for development into a cloning vector and/or mutagenesis vehicle in *M. pulmonis*. It should be emphasized that IS*1138* is species-specific to *M. pulmonis*, but it is ubiqutous among its strains (Bhugra and Dybvig 1993).

Another species-specific IS element is IS*1634* that belongs to the IS4 family. It was identified in *M. mycoides* subsp. *mycoides* SC. This pathogenic mycoplasma is distinguished by its exceptionally high number of insertion elements. Its genome was found to carry about 30 copies of IS*1634*, and about 20 copies of another, less specific, IS*1296* element, comprising together about 7 percent of the total genomic DNA (Vilei et al. 1999). One may speculate that the numerous copies of these elements play a role in regulating the expression of the organism's genetic potential, including invasion ability into host tissues, characterizing this highly virulent mycoplasma (Vilei et al. 1999). A new type of IS element, named IS1630, was discovered in *M. fermentans* by Calcutt et al. (1999a). It belongs to the IS30 family of transposons and has the striking ability to target and duplicate inverted repeats of variable length and sequence during transposition. In addition, the IS elements may influence gene expression, either by directly inactivating genes upon insertion or by providing promoters that increase the transcription of downstream genes. Insertion of IS-like elements into mycoplasma genomes can be expected to mediate high-frequency genomic rearrangements. In fact, chromosomal rearrangement activity accompanied insertion of specific IS-like elements into the chromosome of clinical isolates of *M. fermentans*. Insertion occurred at extremely high frequencies, as detected by genomic hybridization analysis of randomly subcloned colonies (Hu et al. 1998).

More recently, *M. fermentans* was also found to carry a large (approximately 23 kb) genetic element that is present in four copies in the *M. fermentans* PG18 chromosome, accounting for approximately 8 percent of the genome (Calcutt et al. 2002). These novel elements resemble conjugative, self-transmissible, integrative elements (named constins) and, surprisingly, are devoid of known integrases, transposases, or recombinases, suggesting that a novel enzyme may be employed in excision and integration of these large elements. The skewed distribution and varied sites of chromosomal integration of the elements among *M. fermentans* isolates, and in two other mycoplasma species, suggest that these elements play a role in promoting genomic and phenotypic variations in mycoplasmas.

PATHOGENICITY

Most mollicutes live as commensals, and in many arthropods they may even be considered as symbionts. In the case of pathogenic mycoplasmas, infections are rarely of the fulminant type, but rather follow a chronic course. Extensive descriptions of the diseases caused by mollicutes to humans, animals, plants, and insects can be found in *The Mycoplasmas* volume IV (Razin and Barile 1985) and volume V (Whitcomb and Tully 1989), in Maniloff et al. (1992) and in Razin and Herrmann (2002).

A variety of human diseases of unknown etiology, are also linked to mycoplasmas. These include the possible role of mycoplasmas as cofactors to AIDS pathogenesis, the Gulf War syndrome, and other diseases of unexplained etiology, such as chronic fatigue syndrome, fibromyalgia, Crohn's disease, and various arthritides (Baseman and Tully 1997; Endresen 2003; Lo et al. 2000). While the association of mycoplasmas with many of these diseases remains doubtful, the possible role of

mycoplasmas in AIDS activation attracted the most attention during the 1990s. The substantial number of studies carried out on the AIDS-associated mycoplasmas, *M. fermentans* and *M. penetrans*, have considerably advanced our knowledge of mycoplasma cell biology and host immune modulation by mycoplasmas, as evidenced in many sections of this chapter. However, the proposed role of mycoplasmas in AIDS activation remains controversial and doubtful (Baseman and Tully 1997; Brenner et al. 1996; Taylor-Robinson and Furr 1998). Mycoplasmas were suspected long ago to be causative agents of rheumatoid arthritis (RA), but solid evidence to support this was lacking. The recent emphasis on the immunomodulatory effects by mycoplasmas (see Immune system modulation section) and more so, detection of mycoplasmal DNA, particularly that of *M. fermentans*, in synovia of RA patients (Schaeverbeke et al. 1999), as well as the prevalence of antibodies to *M. fermentans* in the patients (Horowitz et al. 2000) suggest that in some RA patients *M. fermentans* may play a role in initiating or perpetuating synovitis (Blanchard and Bebear 2002).

Disease manifestations

Table 2 presents the sites of colonization and pathogenicity of mollicutes infecting humans. The best established human pathogen is *M. pneumoniae*. The effects of *M. pneumoniae* on humans include subclinical infection, upper respiratory disease, and bronchopneumonia (reviewed by Jacobs, 2002; Talkington et al. 2001). Most human infections do not progress to a clinically evident pneumonia. When pneumonia occurs, the onset is generally gradual and the clinical picture is one of a mild to moderately severe illness, with early complaints referable to the lower respiratory passages. Radiography frequently reveals evidence of pneumonia before physical signs are apparent. Involvement is usually limited to one of the lower lobes of the lungs, and the pneumonia is interstitial or bronchopneumonic. The course of disease varies; remittent fever, cough, and headache persist for several weeks. One of the most consistent clinical features is long convalescence, which may extend from 4 to 6 weeks. Several infrequent complications following *M. pneumoniae* infections have been noted, including hemolytic anemia, polyradiculitis, encephalitis, aseptic meningitis, and central nervous system illness such as Guillain–Barré syndrome. In addition, pericarditis and pancreatitis have been observed. Although these sequelae have been commonly related to the suspected immunopathology of *M. pneumoniae* disease, *M. pneumoniae* has been increasingly demonstrated in the affected organs by PCR, or in some cases even by culture (Narita et al. 1995; Bencina et al. 2000).

Growing evidence suggests that *Ureaplasma urealyticum* causes nongonococcal urethritis in men free of *Chlamydia trachomatis*, an established agent of nongonococcal urethritis. The wide occurrence of *U. urealyticum* in sexually active, symptom-free adults hampers research in this field. Evidence is based primarily on the production of nongonococcal urethritis symptoms in ureaplasma-free and chlamydia-free volunteers by intraurethral inoculation of *U. urealyticum* (Taylor-Robinson and Furr 1998). Ureaplasmas have also been associated with chorioamnionitis, habitual spontaneous abortion, and low-weight infants (Gerber et al. 2003). *Mycoplasma hominis*, a common inhabitant of the vagina of healthy women, becomes pathogenic once it invades the internal genital organs, where it may cause pelvic inflammatory diseases, such as tubo-ovarian abscess or salpingitis (Taylor-Robinson and Furr 1998).

It has been suggested that *Mycoplasma genitalium*, isolated in 1981 from the urethral discharge of two homosexual men, may account for the tetracycline-responsive, nongonococcal urethritis cases in which chlamydias and ureaplasmas could not be isolated (about 20 percent of all cases). However, *M. genitalium* is so fastidious that very few clinical isolates have so far been made on the best mycoplasma media available. Only the more recent application of specific PCR amplification of the organism's DNA in clinical specimens has provided experimental proof for the relative prevalence of *M. genitalium* in the human urogenital tract and its apparent role in chronic male urethritis (Taylor-Robinson and Furr, 1998; Totten et al. 2001) and possibly also in acute endometritis and cervicitis in women (Cohen 2002; Manhart et al. 2003).

Many *Mycoplasma* species are established pathogens of farm animals, causing contagious pleuropneumonia, mastitis, and conjuctivitis in cattle, goats, and sheep, and chronic respiratory disease and arthritis in swine, chicken, and laboratory animals (Frey 2002).

Molecular basis of mycoplasma pathogenicity

OXIDATIVE DAMAGE AND MEMBRANE FUSION

Potent toxins have not been associated with mycoplasmas. The mildly toxic byproducts of mycoplasma metabolism, such as hydrogen peroxide and superoxide radicals, have been incriminated as causing oxidative damage to host cell membranes. Extensive studies by Almagor et al. (1986) led to the formulation of the following pathological events of *M. pneumoniae* infection (Figure 9). The H_2O_2 and superoxide radicals (O_2^-) continuously generated by the adhering mycoplasmas penetrate into the host cell. As a result of O_2^- accumulation, gradual irreversible inhibition of host cell catalase is induced, thereby causing intracellular H_2O_2 accumulation. This, in turn, may cause product inhibition of the host cell superoxide dismutase. The process is self-perpetuating and results in increased levels of O_2^- and H_2O_2, which induce progressive oxidative damage

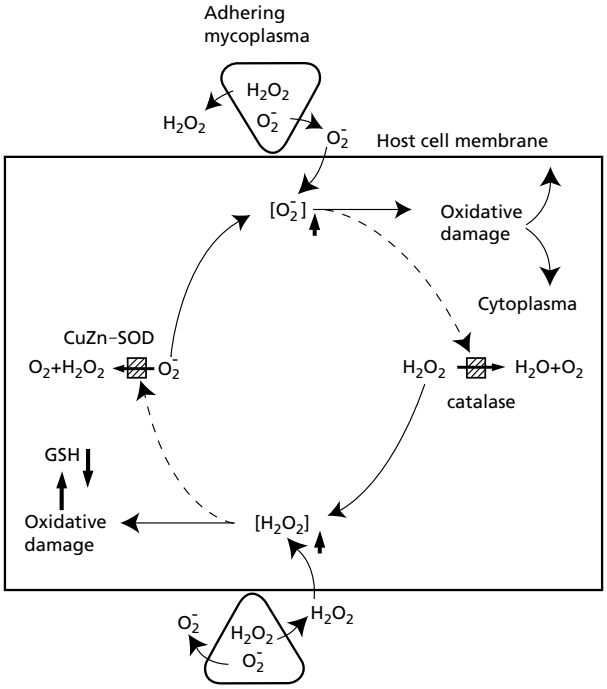

Figure 9 *Schematic presentation of the proposed mechanism for oxidative tissue damage by mycoplasmas. GSH, glutathione; SOD, superoxide dismutase (courtesy of Kahane 1984).*

to vital cell constituents. Thus, malonyldialdehyde, a known oxidative product of membrane lipids, was shown to accumulate in cells infected by *M. pneumoniae*. Supportive of the role of hydrogen peroxide in mycoplasma pathogenicity are the recent findings of Vilei and Frey (2001) showing that the higher virulence of the African strains of *M. mycoides* subsp. *mycoides* SC may be associated with their ability to transport and metabolize glycerol. Peroxide production in glycerol-containing growth media was high for the African strains, but very low for the much less virulent European strains that lack the genes for glycerol transport. A question most frequently asked is how the mycoplasmas, lacking antioxidants like catalase and superoxide dismutase, protect themselves against oxidative stress. The finding by Dhandayuthapani et al. (2001) of methionine sulfoxide reductase in *M. pneumoniae* and *M. genitalium*, an antioxidant enzyme that catalyzes the reduction of methionine sulfoxide residues in proteins to methionine, may play an important role in protecting mycoplasma protein structure from oxidative damage.

The lack of a cell wall in mycoplasmas is expected to facilitate direct contact of the mycoplasma membrane with that of its eukaryotic host, creating a condition which, in principle, could lead to fusion of the two membranes, enabling transfer or exchange of membrane components and 'injection' of mycoplasmal cell constituents into the host cell (Razin et al. 1998; Rottem 2002c). Unique *M. fermentans* glyceroglycolipids containing phosphocholine (Rottem 2002a) exhibit fusogenic properties, in addition to serving as important surface immunogens, inducing cytokine secretion. The possibility that the synthesis of the choline-containing lipids by *M. fermentans* may cause choline depletion in the host has been brought up by Ben-Menachem et al. (2001). Choline is an essential component of eukaryotic cell membranes. *M. fermentans* was found to deplete the choline component of an astrocyte cell culture leading to apoptosis of the cells, an effect that could be prevented by the addition of free choline to the growth medium. Whether choline deficiency can occur in patients infected by *M. fermentans* is obviously a moot point.

INTRACELLULAR LOCATION

Human and animal mycoplasmas were shown to be taken up by polymorphonuclear leukocytes and macrophages (Marshall et al. 1995), and intracellular location of spiroplasmas and phytoplasma within salivary gland cells of insects is an integral part of their life cycle. However, the question of whether animal mycoplasmas can enter epithelial cells has not been easy to resolve, and for a long time this question was answered in the negative. The stimulus to re-examine this issue came from the studies by Lo (1992) showing the intracellular location of *M. fermentans* (strain incognitus) in a variety of nonphagocytic cells in AIDS patients. This finding was strengthened by the discovery of a new human mycoplasma capable of entry into a variety of human cells in vivo and in vitro, named accordingly *M. penetrans* (Lo et al. 1993).

The mechanism of cell entry by mycoplasmas is still unclear. While mycoplasmas, such as *M. penetrans* and *M. genitalium* appear to enter the cells through their specialized tip structure (Jensen et al. 1994; Lo et al. 1993), other mycoplasmas shown to internalize, such as *M. fermentans* and *M. hominis*, have no tip structures (Taylor-Robinson et al. 1991). Following contact of *M. genitalium* with human lung fibroblasts the plasma membrane of the cells appeared to be forced inward to form a cup or a depression. The membrane pockets resembled clatherin-coated pits, suggesting that the mycoplasma might adhere to and enter the cells by a site-directed, receptor-mediated event, resembling cell entry by chlamydia (Mernaugh et al. 1993). Host cell entry appears to depend on the assembly of actin microfilaments and organized microtubules, as cytochalasin D prevented invasion by *M. penetrans* (Rottem 2002c). It appears that *M. penetrans* stimulates host cell phospholipases to cleave membrane phospholipids, thereby initiating a signal transmission cascade. This cascade triggers cytoskeletal rearrangements, allowing the internalization of *M. penetrans*. The presence in the host cell cytoplasm of mycoplasmas, some of which may not even be enclosed within a vacuole, may expose the cytoplasm and the nucleus to mycoplasmal hydrolytic enzymes, such as proteases, nucleases, and phospholipases (Rottem 2002c).

Whether the internalized mycoplasmas replicate intracellularly remains to be resolved. The study by Dallo and Baseman (2000) indicated that intracellular *M. pneumoniae* and *M. penetrans* infectivity in human cells could be detected for over 6 months, while *M. genitalium* survival in the cells was detected by PCR for long periods. Moreover, specific inhibition of eukaryotic nuclear DNA synthesis by aphidicolin enabled the selective detection of mycoplasmal DNA synthesis, supporting their intracellular replication (Dallo and Baseman 2000).

It should be emphasized that intracellular location, if even for a short period, may protect the mycoplasmas against the effects of the host immune system and antibiotics, and to some extent account for the difficulty of eradicating mycoplasmas from infected cell cultures. Thus, intracellular residence, which sequesters mycoplasmas, promotes the establishment of latent or chronic infection states, and circumvents mycoplasmacidal immune mechanisms and selective drug therapies (Bebear and Bebear 2002). Different aspects of the interaction of mycoplasmas with host cells, including fusion of the parasite with the host cell membrane, invasion into host cells, and the implications of these processes on mycoplasma pathogenicity, have been recently reviewed in depth by Rottem (2003).

CLASTOGENIC AND ONCOGENIC EFFECTS

The potent mycoplasmal nucleases, combined with superoxide radicals, may be responsible for clastogenic effects. In fact, reports on chromosomal aberrations, altered morphology, and cell transformation in cell cultures infected by mycoplasmas have appeared rather sporadically since the early 1960s. Interest in this subject has been rekindled recently following the claims that *M. penetrans* may be a cofactor in the induction of HIV-associated Kaposi's sarcoma. Results of experiments with cultured mouse embryo cells reported by Tsai et al. (1995) appeared to support an oncogenic potential of the AIDS-associated mycoplasmas *M. fermentans* and *M. penetrans*. However, instead of acute transformation, a multistage process in promotion and progression of malignant cell transformation with long latency was noted. Only after 18 passages (1 week per passage) of persistent infection with mycoplasmas, an irreversible form of transformation, that included the ability to form tumors in mice, was achieved. It should be pointed out, however, that the tumors had developed very slowly and not in all mice. The irreversible phase of transformation coincided with permanent karyotypic alterations. Once induced, chromosomal alterations continued to accumulate both in cultured cells and in animals without the continued presence of the transforming mycoplasmas. Hence, the mycoplasma-mediated multistage oncogenesis exhibited many characteristics found in the development of human cancer (Lo 2002). Nevertheless, the real biological significance of these findings warrants further investigation.

Another related issue concerns the induction of apoptosis by mycoplasma infection (reviewed by Lo 2002). DNA fragmentation, a common biochemical hallmark of apoptosis, is generally considered to be catalyzed by endogenous endonucleases. In light of the relatively large amounts of nucleases expressed by mycoplasmas (Bendjennat et al. 1999), Paddenberg et al. (1998) tested the effects of *M. hyorhinis* infection of NIH 3T3 cells, checking for parameters characteristic of apoptosis. The infected cells exhibited intranucleosomal DNA degradation into multimers of 200 bp, forming a ladder in agarose gels. Nuclease activities were detected in cell homogenates and culture supernatants. Their mycoplasmal origin was indicated by inhibition of their expression following chloramphenicol treatment of the infected cells. Furthermore, enriched mycoplasmal nucleases, purified from culture supernatants of *M. hyorhinis* and *M. penetrans* could reproduce the apoptotic effects of mycoplasmal infection (Paddenberg et al. 1998; Bendjennat et al. 1999). Apoptotic effects were also observed in lymphocyte and epithelial tumor cell lines infected by mycoplasmas, pointing to the possibility that the numerous cases of 'spontaneous apoptosis' reported in cell cultures are, in fact, the results of an undetected mycoplasma infection (Paddenberg et al. 1998; Stolzenberg et al. 2000). The finding that *U. urealyticum* induces apoptosis in human lung epithelial cells and macrophages may support the proposed role of the ureaplasmas in chronic lung disease of premature infants (Li et al. 2002). Some insight into the mycoplasmal cell components that induce apoptosis has been presented by Into et al. (2002) showing that mycoplasmal membrane lipoproteins induce necrotic and apoptotic cell death in monocytes/macrophages and lymphocytes. Apoptosis was induced by caspases (cysteine proteases) through Toll-like receptor 2 (TLR2)-mediated signaling.

PATHOGENICITY-ASSOCIATED GENES

A promising genetic approach, based on transposon *Tn4001* mutagenesis, has been applied to study pathogenicity factors of *S. citri* (Foissac et al., 1997; Gaurivaud et al. 2000a, b). One of the *Tn4001* mutants did not multiply in the leafhopper vector and, therefore, could not be transmitted to the plant. Another mutant multiplied well in the plant, but did not induce symptoms. It was found that in this nonpathogenic mutant, *Tn4001* was inserted in the spiroplasmal fructose PTS operon, abolishing the ability of the spiroplasma to utilize fructose, probably affecting in this way its pathogenicity. The most likely explanation is that utilization of fructose in the plant sieve tubes by the pathogenic spiroplasmas may interfere with the normal physiology of the plant causing chlorosis, stunting, and wilting (Bai and Hogenhout 2002). It would be of interest to test if

pathogenicity of the mutant can be restored by complementation with the wild-type genes, like the successful restoration of motility in a *Tn4001 S. citri* mutant by complementation with the wild-type genes (Jacob et al. 1997; see Motility section). Continuing this line of research, Jagoueix-Eveillard et al. (2001) embarked on the study of plant genes that are deregulated following infection by mollicutes. These rather preliminary studies revealed that cDNAs of periwinkle plants are differently expressed following infection with *S. citri* or by phytoplasmas. Clearly, much more work has to be carried out to identify the metabolic pathways modified during plant–mollicute interactions, but the genetic approach appears to be very promising.

The lysogenic bacteriophage MAV1 infecting *M. arthritidis* (Voelker and Dybvig 1999; Washburn and Cole 2002) appears to play an important role in the pathogenicity of this murine mycoplasma. All virulent *M. arthritidis* strains carry MAV1 DNA integrated at various sites of the mycoplasmal chromosome, while avirulent strains lack MAV1. Furthermore, the arthritogenic potential of a low-virulence *M. arthritidis* strain could be considerably enhanced by lysogenization with MAV1. The mechanism by which MAV1 enhances virulence is not known. The fact that several MAV1-negative strains are not completely avirulent suggests that MAV1 integration may activate other virulence factors, such as the *M. arthritidis* superantigen MAM (Washburn and Cole 2002), or increase the expression of *M. arthritidis* cytadhesins. The recent identification in MAV1 of a gene, named *vir*, apparently encoding for a lipoprotein, may provide some direction to future research, assuming that the phage-derived lipoprotein is incorporated into the cell membrane of the avirulent *M. arthritidis*, inducing in some unknown way the conversion of the avirulent to the virulent phenotype (Voelker and Dybvig 1999; Tu et al. 2002).

Adhesion to host cells

Most human and animal mycoplasmas adhere tenaciously to the epithelial linings of the respiratory or urogenital tract, rarely invading tissues. Hence, they may be considered as surface parasites. Adhesion of mollicutes to host cells is a prerequisite for colonization by the parasite and for infection. The loss of adhesion capacity by mutation results in loss of infectivity, and reversion to the cytadhering phenotype is accompanied by regaining infectivity and virulence. The best-defined mycoplasmal cytadhesins are those of *M. pneumoniae* and *M. genitalium*. Detailed information on the genes and molecular properties of the encoded cytadhesin proteins of these mycoplasmas (P1, MgPa, and P30) can be found in several reviews (Razin and Jacobs 1992; Razin et al. 1998; Krause and Balish 2001; Balish and Krause 2002).

Although the above-mentioned cytadhesins fulfill the major role in cytadhesion of *M. pneumoniae* and *M. genitalium*, the process appears to be multifactorial, involving in addition to the major cytadhesins, a number of 'accessory' membrane proteins. These 'accessory' proteins act in concert with cytoskeletal elements to facilitate the lateral movement and concentration of the cytadhesin molecules at the attachment tip organelle and provide the scaffolding for the assembly of this organelle (see Cellular morphology and cytoskeletal elements section). Much of the recent effort, forming part of the *M. pneumoniae* genome project, has been directed to the molecular definition of the attachment organelle components, forming part of the mycoplasmal cytoskeleton ('Triton shell'). Some of the genes and the encoded proteins of the *M. pneumoniae* Triton shell (30 kDa; 40 kDa; 90 kDa; P65; P200; HMW1; HMW2, HMW3) have been identified and characterized (Table 5) and have recently been compared to their homologs in *M. genitalium* (Dhandayuthapani et al. 2002). Interestingly, the proteins are proline rich and exhibit repeat sequences and other motifs reminiscent of eukaryotic cytoskeletal proteins. Thus, the C-terminal domain of P30 shows substantial sequence homology with the C-terminus of P1 and exhibits immunological cross-reactivity with fibrinogen, keratin, and myosin, a finding which may be associated with the autoimmune sequelae following *M. pneumoniae* infections (Romero-Arroyo et al. 1999).

The HMW1 protein appears to be responsible for targeting (trafficking) the P1 adhesin to the attachment organelle (Balish et al. 2001) while the 40- and 90-kDa proteins anchor P1 to the membrane of the organelle in a way that allows mutual and intimate interactions of P1

Table 5 M. pneumoniae *membrane and cytoskeletal proteins associated with cytadherence*[a]

Protein	Size (kDa)	Features and presumed role of protein
P1	169	Major adhesin, proline-rich C-terminus
P30	30	Adhesin, proline-rich C-terminus
HMW1	112	Cytoskeletal protein, targeting P1 to attachment tip
HMW2	216	Cytoskeletal coiled-coil protein at attachment tip
HMW3	74	Terminal button and core shaft of attachment tip
B	90	Scaffolding role, anchoring P1 to attachment tip
C	40	Scaffolding role, anchoring P1 to attachment tip
P65	47	Surface protein, proline-rich acidic domain
P200	117	Cytoskeletal protein, role in cytoadherence is uncertain

a) For details see Balish and Krause (2002).

with cytoskeletal forming or associated proteins. Loss of the 40- and 90-kDa proteins by mutation results in the loss of the attachment organelle, cells becoming spherical, and nonadherent (Layh-Schmitt and Harkenthal 1999). The genes for HMW1, HMW3, and P65 are part of the *hmv1* locus, along with the gene for P30. The *hmv2* gene for HMW2 lies about 160 kb from the *hmw1* locus. Yet, transposon insertions into *hmw2* resulted in the simultaneous loss of HMW1, HMW3, and P65, as well as of several other cytadherence-associated proteins, probably due to accelerated endogenous proteolysis (Krause and Balish 2001; Jordan et al. 2001). Thus, it appears that HMW2 functions as a cytoskeletal organizer and is required for the stable maintenance of the above proteins (Fisseha et al. 1999). The complex interrelationships between the components of the attachment organelle underscores the need for the proper ordered assembly of this organelle that must also be coordinated with cell division (Fisseha et al. 1999; Krause and Balish 2001; Seto et al. 2001).

The avian pathogen *M. gallisepticum* also carries an attachment organelle (Figure 6) and its cytadherence, like that of *M. pneumoniae*, is a complex multifactorial process involving the coordinate action of a primary cytadhesin molecule GapA and several additional cytadherence-associated proteins in a manner reminiscent of the complex cytadherence mechanism of *M. pneumoniae*. The gene *crmA* (cytadherence-related molecule A), located immediately upstream of *gapA*, has significant sequence homology to the ORF6 of the *M. pneumoniae* P1 operon (Mudahi-Orenstein et al. 2003; Papazisi et al. 2000; Winner et al. 2003) and must be present together with GapA to mediate cytadherence of *M. gallisepticum* (Papazisi et al. 2002a). An *M. gallisepticum* gene encoding a 105 kDa protein, showed 45 percent homology to the *M. pneumoniae* P1 gene, 46 percent homology to the *M. genitalium* MgPa adhesin gene, and 47 percent homology to the *M. pirum* P1-like protein gene (Goh et al. 1998). Along the same line, the P30 adhesin gene of *M. pneumoniae* shows 40.9 percent identity with the 32 kDa protein gene of *M. gallisepticum*, and 31.4 percent identity with the *M. genitalium* P32 cytadhesin gene (Hnatow et al. 1998). Collectively, these findings suggest the presence of a family of cytadhesin genes conserved among the pathogenic mycoplasmas belonging to the pneumonia phylogenetic clade. One may speculate that these cytadhesin genes originate from the same ancestral operon.

M. hyopneumoniae adheres to the cilia of the respiratory epithelium of swine (Young et al. 2000). The gene coding for the ciliary cytadhesin was cloned and sequenced and its 97 kDa protein product was characterized (Minion et al. 2000). The R1 region near the carboxy terminus of the protein mediates the adhesion of the mycoplasmas to the cilia. Eight R1 repeating units are required for cilia binding. Interestingly, *M. flocculare*, genetically closely related to *M. hyopneumoniae*, lacks the 97 kDa ciliary cytadhesin gene (Blank and Stemke 2001), possibly explaining the lack of pathogenicity of this mycoplasma to swine. Cytadherence of *M. hyopneumoniae* causes a fast increase in the intracellular free Ca^{2+} concentration in the infected porcine ciliated tracheal epithelial cells probably causing damage and loss of the ciliary epithelium (Park et al. 2002).

The receptors on the host cell membranes responsible for mycoplasma attachment, identified so far, are mostly sialoglycoconjugates and sulfated glycolipids (Kitzerow et al. 1999; Razin and Jacobs 1992; Zhang et al. 1994). The glycoprotein fibronectin, known to serve as a host receptor in the binding of streptococci, staphylococci, mycobacteria, borrelia, and treponema appears also to serve as a receptor in the binding of *M. penetrans* (Giron et al. 1996) and of *M. pneumoniae* (Dallo et al. 2002). Somewhat unexpected was the identification of the cytoplasmic elongation factor Tu and the E1β subunit of pyruvate dehydrogenase as the mycoplasmal fibronectin binding proteins. It appears that the *M. pneumoniae* EF-Tu and the pyruvate dehydrogenase subunit, in addition to their major cytoplasmic biosynthetic and metabolic roles, can be translocated to the cell surface and show multifunctionality. Along this line is the recent identification of glyceraldehyde-3-phosphate dehydrogenase of *M. genitalium* acting, in addition to its important metabolic role, as an adhesin to host cell surface mucin (Alvarez et al. 2003). It is worth mentioning that Layh-Schmitt et al. (2000) detected the E1α subunit of pyruvate dehydrogenase as part of a crosslinked complex of the *M. pneumoniae* cytadhesins. What is the weight to be given to the fibronectin cytadhesion system when compared to the well-established specific cytadhesin system (P1, P30, etc.) described above? Does the novel system fulfill an auxilliary role in mycoplasmal attachment to host cells? Obviously, these are issues that require further study.

It may not be surprising that the surface exposed cytadhesin proteins are amongst the most immunodominant mycoplasmal antigens. Furthermore, at least some mycoplasmal cytadhesins, for example, the Vaa proteins of *M. hominis* (Kitzerow et al. 1999), the Vsp proteins of *M. bovis* (Sachse et al., 2000), the MMA2 protein of *M. arthritidis* (Washburn et al. 1998), the pMSA and pMSB hemagglutinins of *M. synoviae* (Bencina et al. 2001), as well as certain hemagglutinnins of *M. gallisepticum* (Boguslavsky et al. 2000) (Table 6) exhibit the phase- and size-variation properties to be discussed in the next section.

Antigenic variation

The mycoplasma plasma membrane, being exposed to the external environment, is the cell organelle that comes into contact with the constituents of the host immune system. Lacking the protection of a rigid cell wall, mycoplasmas are particularly sensitive to growth

Table 6 *Surface variable antigenic systems in mycoplasmas*

Organism	Genes involved	System components	Mechanism of variation
M. hyorhinis	*vlp* gene family	Lipoproteins	Strand slippage (poly A) Yogev et al. (1991a)
M. bovis	*vsp* gene family	Lipoprotein, chimeric lipoprotein	Site-specific inversions homologous recombination (Lysnyansky et al. 2001; Flitman-Tene et al. 2003)
M. agalactiae	*avg* gene family	Lipoproteins	
M. gallisepticum	PMGA (*vlh*) gene family	Lipoproteins	Strand slippage (GAA) (Glew et al. 1998)
	pvpA (single copy)	Integral protein (not lipid-modified adhesin)	Point mutation (GAA) (Boguslavsky et al. 2000)
M. hominis	*lmp* gene family	Lipoproteins (p120; p135)	Unknown; phase-variable masking (Ladefoged and Christiansen 1998)
	vaa single copy gene	Lipoprotein adhesin	Strand slippage (poly A) (Zhang and Wise 1997)
M. fermentans	P78/part of an ABC transporter operon	Lipoprotein	Strand slippage (poly A)(Theiss and Wise 1997)
	malp single copy gene	Lipoprotein	Posttranslational modification (Calcutt et al. 1999b)
M. penetrans	*mpl* genes (P35, P34A,P34B,P38)	Lipoproteins	Promoter inversion (Horino et al. 2003)
M. arthritidis	*maa2* single copy gene	Lipoprotein adhesin	Strand slippage (poly T) (Washburn et al. 1998)
M. mycoides subs. *mycoides* (SC)	*vmm* gene	Lipoprotein	Strand slippage $(TA)_n$ insert in promoter region (Persson et al. 2002)
M. synoviae	*vlh* pseudogene family	Chimeric lipoproteins adhesins	Gene conversion (Noormohammadi et al. 2000)
M. pulmonis	*vsa* gene family	Lipoproteins	Site-specific inversions (Shen et al. 2000)

inhibition and lysis by antibodies and complement. Yet, despite this marked sensitivity, mycoplasma infections are usually chronic in nature, indicating the frequent failure of the host defense mechanisms to eradicate the parasites. It appears that many pathogenic mycoplasmas possess rather sophisticated mechanisms for rapid adaptation to changing microenvironments. Reversible switching of the expression and modification of major membrane protein antigens on the mycoplasma surface provides an effective escape from rapid destruction by the host immune system (reviewed by Yogev et al. (2002)). Considering the chronic nature of mycoplasmal infections, it would appear that the constant selection of subpopulations, rather than adaptation of an entire population to an environmental change, is responsible for the heterogenous populations of these organisms.

Table 6 presents the mycoplasmal antigenic variation systems studied thus far. The data enable some generalizations to be made: (1) Most of the systems consist of lipoproteins exposed on the external cell surface and anchored to the membrane via acyl chains. (2) The lipoproteins, functioning as dominant cell antigens, carry repetitive sequences that can spontaneously vary in size through changes in the number of these motifs (size variation). Moreover, the lipoproteins vary not only in size, but may be subjected to 'on' and 'off' expression states (phase variation). (3) Cloning and sequencing of the lipoprotein genes has revealed that the encoded proteins consist of three regions: the N-terminal leader region, an intermediate domain, and the C-terminal domain comprising of reiterated sequences arranged in tandem. Deletion of the leader sequence on processing of the protein leaves a cysteine residue at the N-terminus free for acylation, preferentially by palmitic and myristic acids. The resulting lipid-modified protein is enchored to the outer surface of the membrane through its lipid moiety. (4) In most cases, each mycoplasma strain carries a family of lipoproteins, encoded by multiple variant genes in several versions. The genes are expressed in various combinations and at varying lengths on the organism's surface. Interestingly, in the case of a large family of genes, only one or two genes are expressed at a given time, the others are translationally silent (Bhugra et al. 1995; Glew et al. 1998; Lysnyansky et al. 1999; Sasaki et al. 2002). (5) In many cases, the surface exposed lipoproteins also function as cytadhesins (Table 6).

The microbial population as a whole may spontaneously and randomly generate distinct cell populations with varied antigenic phenotypes, 'heterotypes', that will

survive the specific host response capable of eliminating the predominant 'homotypes'. The frequency of occurrence of such genetic variants is strikingly high (10^{-4}–10^{-2} per cell per generation, compared to 10^{-6}–10^{-8} of a normal occurring mutation). Lipoproteins may not be the only variable mycoplasma membrane proteins exposed on the cell surface. Thus, the *M. gallisepticum* PvpA is a non-lipid modified, integral phase-variable membrane protein (Boguslavsky et al. 2000; Yogev et al. 2002). Nevertheless, this mycoplasma carries in addition a highly immunogenic lipoprotein, pMGA, undergoing high-frequency phase variation spontaneously and independently (Glew et al. 1998). There is solid experimental evidence for the occurrence of antigenic variation in vivo. Thus, multiple isolates of *M. hominis* obtained from the same joint of a septic arthritis patient during a 6-year period, exhibited antigenic variation, although the strains were indistinguishable by restriction endonuclease analysis (Olson et al. 1991). Field infections of sheep and goats by *M. agalactiae* (Flitman-Tene et al. 2000) and chicken by *M. gallisepticum* (Glew et al. 2000) indicate that high-frequency antigenic phase variation occurs in vivo.

VARIATIONS IN THE *M. PNEUMONIAE* P1 AND P30 ADHESIN GENES

A hot spot for frequent mutation within a structural gene was found in the major cytadhesin gene (P1) of *M. pneumoniae*. Reversible and spontaneous cytadherence-negative and cytadherence-positive mutants were associated with an insertion or deletion of a single nucleotide in a stretch of seven adenines. This mutation resulted in a frameshift and generation of a termination codon causing the premature termination of P1 translation (Su et al. 1989). Large portions of the coding regions of the *M. pneumoniae* P1 operon exist as multiple extragenic copies over the chromosome, named RepMP2/3, Rep MP4, originating in the P1 gene, and Rep MP5 originating in the ORF6 gene of the P1 operon. Relics of these sequences detected in *M. genitalium*, named MgPa repeats, revealed strong sequence similarities to the repetitive DNA sequences from *M. pneumoniae* (Himmelreich et al. 1997). Clinical isolates of *M. pneumoniae* were found to exhibit some nucleotide sequence variation in the P1 gene (Dorigo-Zetsma et al. 2000, 2001). The variable regions in the gene were found to correspond to regions of some of the repetitive elements, suggesting that the P1 gene may vary due to recombination between repetitive regions (Kenri et al. 1999; Su et al. 1993). Accordingly, the *M. pneumoniae* strains have been divided into two groups, I and II (Su et al. 1993).

The 30 kDa (P30) adhesin protein of *M. pneumoniae* also appears to undergo size variation, losing proline-rich repetitive sequences in its C-terminal region. The truncated adhesin showed reduced antigenicity and adhesion capacity. The mechanism underlying the loss of the repeated sequences is not clear, but slipped base pairing during replication or homologous recombination processes between repeated sequences might be the cause of size polymorphism (Layh-Schmitt et al. 1997).

The different genetic mechanisms that form the genetic basis for antigenic variation, including strand slippage, homologous recombination, gene conversions, gene duplications, addition or deletion of tandem repetitive units, and DNA inversions (Table 6) are discussed in detail by Razin et al. (1998) and by Yogev et al. (2002).

Immune system modulation

The complex network of interactions between mycoplasmas and their host immune system involves mycoplasma-induced specific and nonspecific immune reactions. Specific protective defense mechanisms include the production of systemic as well as local anti-mycoplasmal antibodies of different classes and subclasses, stimulation of cell-mediated immunity, and opsonization and phagocytosis of organisms. In some cases, in order for macrophages to kill invading mycoplasmas, some accessory factors provided by the host are required. Thus, alveolar macrophages serving as the primary effector cells in early *M. pulmonis* killing in infected mice depend on the presence in the lungs of the collectin surfactant protein A. Nitric oxide and superoxide radicals produced by the macrophage contribute to the killing either directly or via the production of peroxynitrite ($ONOO^-$) (Hickman-Davis et al. 1999).

The specific reactions elicited by invading mycoplasmas, essential for resistance and protection against mycoplasma infections, have also been shown to play a role in the development of lesions and exacerbation of mycoplasma-induced diseases (Razin et al. 1998). Humoral immunity has a major role in defense against systemic dissemination of mycoplasmal infection, but cellular immune responses may be important in exacerbation of mycoplasmal lung disease. Lack of adaptive response in severe combined immunodeficient (SCID) mice infected with *M. pulmonis* was associated with reduced lung lesion severity and with increased mycoplasmal colonization and disease at extrapulmonary sites. The transfer of naïve spleen cells from immunocompetent mice to *M. pulmonis*-infected SCID mice restored the severity of lung lesions, while the transfer of convalescent anti-*M. pulmonis* serum to the infected SCID mice did not restore lung lesion severity, but prevented arthritis (Cartner et al. 1998).

Although mycoplasmas circumvent phagocytosis (Marshall et al. 1995; Minion 2002), they appear to interact with mononuclear and polymorphonuclear phagocytes, suppressing or stimulating them by a combination of direct and indirect cytokine-mediated effects. For extensive recent reviews on cytokine induction by

mycoplasmas, the reader is referred to Razin et al. (1998) and to Rawadi and Roman-Roman (1998). These immunomodulatory influences depend on both the immune cells and on the mycoplasma species involved. Thus, *M. dispar* manages to bypass phagocytosis by bovine alveolar macrophages because it is covered by a polysaccharide capsule which inhibits activation of macrophages and suppresses the production of TNF-α and IL-1 (Almeida et al. 1992). Other mycoplasmas activate monocytes, macrophages, and brain astrocytes and induce secretion of the proinflammatory cytokines TNF-α, IL-1 and IL-6, chemokines (such as IL-8, monocyte chemoattractant protein 1, macrophage inflammatory protein 1α/β, and granulocyte–monocyte colony-stimulating factors (GM-CSF)), prostaglandins, and active oxygen and nitrogen metabolites (Razin et al. 1998; Ribeiro-Dias et al. 1999; Yirmiya et al., 1997).

In addition to eliciting antimycoplasmal immune responses, mycoplasmas exert a wide range of nonspecific immunomodulatory effects upon cells comprising the immune apparatus (Reyes et al. 1999). Mycoplasmas have been shown to affect the immune system by inducing either suppression, or polyclonal stimulation of B and T lymphocytes, induction of cytokines, increasing cytotoxicity of macrophages, natural killer cells and T cells, enhancing expression of cell receptors, and activation of the complement cascade. The ability of mycoplasmas to immunomodulate host immune responsiveness contributes to their pathogenic properties, enabling them to evade or suppress their host defense mechanisms and establish a chronic, persistent infection (reviewed in Razin et al. 1998; Muhlradt 2002). The cytokine network plays a critical role in the maintenance of immune system homeostasis. The overproduction of some cytokines in response to mycoplasma infections may upset the fragile equilibrium and thereby contribute to triggering or aggrevation of autoimmune diseases (Rawadi and Roman-Roman 1998).

Mycoplasmas are able to stimulate as well as suppress lymphocytes in a non-specific, polyclonal manner, both in vitro and in vivo. It appears that mycoplasmal B cell mitogens differ from bacterial lipopolysaccharides (LPS) in that they are able to activate lymphocytes from C3H/HeJ mice, which respond poorly to LPS, and their inducing potential is unaffected by polymyxin (Brenner et al. 1997). Modulation of monocyte/macrophage activity by mycoplasmas has been demonstrated in vitro by augmented TNF-α-mediated tumoricidal activity towards different tumor cell lines (Razin et al. 1998). The proven capacity of many mycoplasmas to trigger the production of proinflammatory cytokines in vivo may account for much of the pathology observed during mycoplasma infections and might also influence the subsequent interactions of these microorganisms with lymphoid cells (Manimtim et al. 2001). Additionally to affecting various subsets of lymphocytes, mycoplasmas and mycoplasma-derived cell components modulate the activities of monocytes/macrophages and natural killer (NK) cells and trigger the production of a wide variety of upregulating and downregulating cytokines and chemokines (Razin et al. 1998; Rawadi and Roman-Roman 1998). Mycoplasma mediated secretion of proinflammatory cytokines, such as TNF-α, IL-1, and IL-6 by macrophages, and of upregulating cytokines by mitogenically stimulated lymphocytes play a major role in mycoplasma-induced immune modulation and inflammatory responses. On the other hand, the ability of some mycoplasmas to induce downregulating cytokines, such as IL-10, IL-13, and possibly also TGF-β may contribute to their ability to evade host immune mechanisms by perturbation of macrophage accessory and phagocytic functions. In this way, decreasing production of proinflammatory cytokines and T-cell proliferation and affecting the balance between different T helper cell subsets. The potential of alternately stimulating or suppressing the immune system would impart a distinct advantage to any pathogen attempting to survive in the hostile and changing environment of the infected host.

As to the mechanism of cytokine induction by mycoplasmas, Rawadi et al. (1998) reported that protein tyrosine kinase is absolutely required by the *Mycoplasma fermentans* lipoproteins (LAMPf) to induce proinflammatory cytokines in monocytic cells. The mycoplasmal membrane lipoproteins bind to a cellular receptor(s) that mediates directly or indirectly protein tyrosine kinase activation. This binding triggers the activation of several signal cascade pathways that lead to the phosphorylation and translocation of transcription factors into the nucleus, resulting in transcription, and/or translation of cytokine mRNAs.

It appears that certain mycoplasmas possess more than a single cell component displaying mitogenic activity, and that mycoplasmal mitogens are not necessarily identical to mycoplasmal cytokine-inducing elements. *M. penetrans* appears to possess several T or B cell mitogens (Brenner et al. 1996; Feng and Lo 1999), including a glycolipid and a major membrane lipoprotein. However, although the mitogenic *M. penetrans* lipoprotein is also highly immunogenic in *M. penetrans*-positive AIDS patients and elicits production of specific antibodies (Lo 1992; Brenner et al. 1996; Feng and Lo 1999), the glycolipid is not recognized in sera of *M. penetrans*-infected individuals.

Of special interest as immunomodulators are the mycoplasmal lipopeptides (MALP) which resemble the classical murein lipoprotein in that they carry a fatty acid-substituted N-terminal S-(2,3-bisacyclooxypropyl) cysteinyl group, but lack the N-acyl long chain fatty acid of the classical bacterial lipoproteins (Muhlradt et al. 1997; Muhlradt 2002). This feature renders these mycoplasmal compounds exceptionally active as in vitro macrophage stimulators. Microgram quantities of the *M. fermentans* MALP-2 were found to stimulate the in vitro, as well as in vivo, release of chemokines from

macrophages, being more potent than LPS on a weight basis (Deiters and Muhlradt 1999; Kaufmann et al. 1999) and the co-administration of MALP-2 with a model antigen resulted in potent enhancement of humoral and cellular antigen-specific immune responses, suggesting the use of the lipopeptide as a promising adjuvant for delivery of vaccine antigens (Rharbaoul et al. 2002). Biogenesis of the MALP-2 lipopeptide from the full-length *M. fermentans* lipoprotein MALP-404 involves the extracellular, site-specific proteolytic processing of the lipoprotein yielding the MALP-2 surface-bound lipopeptide, as well as a stable, released fragment of MALP-404. This defines a new mechanism of 'secretion' in mycoplasmas and a novel means of altering the phenotype of mycoplasmas through posttranslational processing (Davis and Wise 2002). Of phylogenetic interest is the finding that the above mycoplasmal lipoproteins share conserved amino acid motifs with lipoproteins of *B. subtilis*, *Treponema pallidum*, and the relapsing fever *Borrelia* spp. (Calcutt et al. 1999b; Rosati et al. 1999). In summation, the above data indicate that mycoplasmal lipoproteins and lipopeptides are probably the most relevant mycoplasmal components in the early host reaction. The primary target cells are likely to be the alveolar macrophages liberating chemokines that attract further leukocytes. The MALP-2 mediated response being dependent on the signaling molecules Toll-like receptor 2 (TLR2) and the activation of caspases, inducing apoptosis and cell necrosis (Luhrmann et al. 2002; Into et al. 2002; Rawadi 2000).

Another chemically defined immunomodulator, produced by *M. arthritidis*, is MAM, a soluble excreted protein of 26 kDa acting as a superantigen (reviewed in Cole et al. 2000; Washburn and Cole 2002). MAM activates a major fraction of murine T cells and a minor fraction of human T cells, by crosslinking MHC class II to TCR, primarily through zinc-dependent binding to the MHC class II E alpha chain in the mouse and to the DR alpha chain in man (Langlois et al. 2003). Activation of T cells (mainly Vβ6 and Vβ8 TCR subsets in mice and Vβ17 and Vβ3 subsets in humans) induces clonal proliferation and release of lymphokines, including IL-2, IL-4, IL-6, and IFN and nitric oxide (Ribeiro-Dias et al. 2003). It should be emphasized that MAM is the only mycoplasmal superantigen defined thus far. The finding of antibodies to MAM or a portion of the MAM molecule in the sera of RA patients raises the possibility that MAM or MAM-like epitopes crossreactive with MAM may play a role in RA (Cole et al. 2000), but this clearly requires further study before any definite conclusions can be drawn.

Except for the chemically characterized *M. arthritidis* superantigen MAM, the macrophage-stimulating lipopeptides and the phosphocholine-containing phosphoglycolipids of *M. fermentans* (Matsuda et al. 2000; Rottem 2002a) there is a need to identify and isolate additional mycoplasmal cell components that exhibit mitogenic and/or cytokine inducing activities. Likewise, there is very little information on the nature of host cell receptors for the mycoplasmal immune modulators.

EPIDEMIOLOGY AND CONTROL OF INFECTIONS

Transmission

Acquisition of mollicutes can be established by direct contact between hosts or through secondary means, such as aerosols, fomites, food, water, insect vectors, or other carriers, and by nosocomial acquisition, such as organ or tissue transplants (Tully 1996). Many mycoplasmas inhabit the mucous membranes of the respiratory, urogenital, or gastrointestinal tracts of vertebrates, so that the mycoplasmas can be transmitted by direct oral to oral, genital to genital, or oral to genital contact. Thus, mycoplasmas found in the oropharynx may also be found in some cases in the genital tract and vice versa. Respiratory aerosols or fomites apparently play the major role in transmission of respiratory tract mycoplasmas, while neonates can be infected by *U. urealyticum* through in utero infection (Taylor-Robinson and Furr 1998).

Secondary transmission of mycoplasmas can also occur through healthy carriers or through convalescent carriers recovering from acute infections, as apparently occurs in some *M. pneumoniae* respiratory infections in humans (Williamson et al. 1992) and probably in acute and chronic respiratory mycoplasmal diseases in domestic animals. Mollicute transmission after plant grafting of infected tissue to healthy rootstock (Tully and Whitcomb 1992), or through human organ or tissue transplantation have also been described (Tully 1996). Semen contaminated with mycoplasma is an important factor in dissemination of sexually-transmitted diseases in a variety of hosts and should be particularly considered in artificial insemination programs in humans and bovines (Kanakas et al. 1999).

The upper respiratory and genital tracts of human newborns are first colonized with mycoplasmas acquired during passage through the female birth canal. There is now substantial evidence that mycoplasma colonization can occur even earlier in utero by organisms introduced during fertilization or during early pregnancy. Generally, neonatal colonization with both human oral and genital mycoplasmas does not persist and the number and type of mycoplasmas decrease with age. Subsequent reacquisition of the human urogenital mycoplasma flora appears to be directly related to sexual contact (Taylor-Robinson and Furr 1998; Blanchard and Bebear 2002). In vertebrates, acquisition from the maternal genital tract, and in utero transmission (including egg transmission in birds), apparently represents the initial mechanism of infection. Transovarian transmission of spiroplasmas has

been well established in Drosophila species (Williamson et al. 1999).

Host factors also play an important and complex role in determining whether an acquired mycoplasma behaves as a pathogen or is avirulent. Endogenous mycoplasmas may become pathogenic when the human host immune system has been compromised or when surgical intervention or trauma allows mycoplasma commensals to enter the circulation or other host tissues. Common commensals, such as *M. hominis*, *M. salivarium*, and *U. urealyticum* have been shown to induce septicemia and overt mycoplasma invasion of various host tissues and organs, with localization in joints being especially prominent (Blanchard and Bebear 2002).

Since *M. pneumoniae* infections are so common in humans, epidemiological data on these infections are abundant. One of the most puzzling features of *M. pneumoniae* pneumonia is the age distribution of patients. In a survey conducted between 1964 and 1975 of more than 100 000 individuals in the Seattle area, the age-specific attack rate was highest among 5- to 9-year-old children (Foy et al. 1979). Rates of *M. pneumoniae* pneumonia in the youngest age group, 0–4 years old, were about one-half those in school-age children, but considerably higher than in adults. *M. pneumoniae* pneumonia was rarely observed in infants younger than 6 months, suggesting maternally conferred immunity. *M. pneumoniae* accounts for 8–15 percent of all pneumonias in young school-age children. In older children and in young adults, the organism is responsible for approximately 15–50 percent of all pneumonias. Infection with *M. pneumoniae* is worldwide and endemic; it occurs all year round, but shows a predilection for the colder months, apparently because of the greater opportunity for transmission by droplet infection. *M. pneumoniae* appears to require close personal contact to spread; successful spreading usually occurs in families, schools, and institutions. The incubation period is relatively long, ranging from 2–3 weeks. The *M. pneumoniae* disease manifestations and epidemiology have recently been reviewed (Talkington et al. 2001; Jacobs 2002).

U. urealyticum is spread primarily through sexual contact. Colonization has been linked to the frequency of sexual intercourse and the number of sexual partners. Women may be asymptomatic reservoirs of infection (Taylor-Robinson and Furr 1998).

Treatment of infections

The mycoplasmas are sensitive to most broad-spectrum antibiotics, such as the tetracyclines and macrolides, as well as to the newer quinolones, but are resistant to antibiotics that specifically inhibit bacterial cell wall synthesis. Susceptibility profiles of human mycoplasmas to a variety of the 'classical', as well as the newer antibiotics were reviewed by Bebear and Bebear (2002). Recommended guidelines for testing mycoplasma susceptibility to antibiotics are presented by Hannan (2000).

Tetracyclines are widely used in the treatment of genital tract infections, while macrolides are used for respiratory tract infections, mostly by *M. pneumoniae*. Erythromycin, the newer macrolides, the ketolides, and the newer quinolones have equal or sometimes greater activity against mycoplasmas as compared to tetracyclines. Most of the effective antibiotics only inhibit mycoplasma multiplication, and do not kill them. The ketolides and some quinolones have some mycoplasmacidal activity (Taylor-Robinson and Bebear 1997).

Mycoplasmas may develop resistance, either by gene mutation, by acquisition of a resistance gene, or by active efflux of the antimycoplasmal agent (Bebear and Bebear 2002; Pereyre et al. 2002; Raherison et al. 2002; Reinhardt et al. 2002). Thus, integration of the *tetM* gene into the *U. urealyticum* or the *M. hominis* chromosome renders these mycoplasmas resistant to tetracycline. The resistance factor could be transferred from other tetracycline-resistant bacteria by a process resembling conjugation (Roberts and Kenny 1987).

Mycoplasmas may be difficult to eradicate from human or animal hosts or from contaminated cell cultures by antibiotic treatment, either due to resistance of the specific mycoplasma to the antibiotic, lack of mycoplasmacidal activity of the antibiotic, or due to the intracellular location of some of the mycoplasmas. As expected, mycoplasma eradication is particularly difficult in immunosuppressed or immunodeficient patients (Taylor-Robinson and Bebear 1997).

Vaccination

WHOLE CELL VACCINES

The frequent failure of antibiotics and other therapeutic approaches to eradicate mycoplasmas and abort the infectious disease process has led to the conclusion that development of effective vaccines is the most promising approach to control mycoplasma infections. The many efforts to develop effective and safe vaccines to mycoplasmas have been only partially successful. The overall success obtained with formalin-inactivated *M. pneumoniae* vaccines in humans has been extremely disappointing, although inactivated vaccines and live attenuated vaccines have had some success in control of some mycoplasma diseases in animals. No acceptable live vaccine has been developed for human use (reviewed in Ellison et al. 1992). Prior natural infection appears to provide the most effective resistance; however, evidence shows that *M. pneumoniae* infections recur at intervals of several years. These observations suggest that immunity to a single natural infection is of relatively short term, particularly in children, and it may be unrealistic to expect more, or even as much, from artificially induced immunity.

Attenuation of mycoplasma strains tends to reduce virulence and immunogenicity. In most cases, attenuated viable vaccines do not reach the level of protective efficiency required from a commercial vaccine. Killed *M. pneumoniae* vaccines administered intranasally to hamsters are relatively inefficient unless boosted by parenteral inoculation of vaccine (Ellison et al. 1992). Intranasal immunization may be ineffective because the antigenic mass is not retained for a sufficient period in the lungs. On the other hand, parenteral killed vaccines, particularly if combined with adjuvant, do produce adequate protection in terms of reducing pneumonia, although there is only a minimal effect on the number of organisms growing in the lungs. A similar protective effect can be achieved briefly by inoculation with hyperimmune serum. In summary, a single dose of vaccine in a form suitable for clinical use is unlikely to produce lasting immunity to *M. pneumoniae* infection. Stimulation of systemic antibodies may prevent the clinical manifestations of pneumonia, but additional local stimulation with live or killed organisms may be necessary to evoke resistance to colonization.

The advantages of live vaccines are well established, but they frequently suffer from deficiencies. Thus, the live *M. gallisepticum* F-strain provides good protection but may be pathogenic to young chicks. Vaccines based on temperature-sensitive mutants of *M. gallisepticum* are safer than the F-strain, but do not afford the same level of protection. Consequently, Papazisi et al. (2002b) proposed a new approach, based on employing a live, attenuated *M. gallisepticum* strain R_{high} that had lost the *gapA* and *crmA* adhesin genes. Insertion of the adhesin *gapA* gene into the chromosome of the attenuated strain resulted in the expression of a high level of Gap A on the mycoplasma cell surface. Vaccination of chicks with this genetically modified strain produced a high level of antibodies to Gap A, protecting the chicks against infection with the virulent R_{low} *M. gallisepticum*.

PROTEIN VACCINES

An approach worth pursuing is the preparation of vaccines made of antigenic components specifically related to the mycoplasma–host cell interaction, such as mycoplasmal cytadhesins. Guinea pigs preimmunized with purified P1 adhesin protein and subsequently infected with *M. pneumoniae* showed increased levels of *M. pneumoniae*-specific IgG, IgA, and adherence-inhibiting antibodies. However, these animals developed severe lung lesions on challenge, suggesting that it may well be harmful to vaccinate the host with the P1 protein, as it may sensitize the host so that subsequent infection will potentiate host response and lead to a more severe disease (Jacobs et al. 1988; Razin and Jacobs 1992). Another mycoplasmal protein vaccine was developed more recently against *M. hyopneumoniae* (Chen et al. 2001). This vaccine was composed of a recombinant chimera of the nontoxic moiety of *Pseudomonas* exotoxin with a fragment of an *M. hyopneumoniae* cytadhesin overexpressed in *E. coli*. The serological response of pigs to this chimeric protein was promising, but more work is needed to show the effectivity of this vaccine under field conditions.

DNA VACCINES

Genetic immunization (DNA vaccines) is a novel, promising approach to vaccine production that has many of the advantages of live/attenuated vaccines, but with no risk of infection. There is no need for confounding factors, such as adjuvants, hapten carriers, or denaturing agents. It involves introducing DNA encoding a pathogen protein into host cells, using an expression library of the pathogen. The first step in the process is the successful transfection of cells that take up the plasmid. The cDNA, with a strong mammalian promoter in the construct, directs the synthesis of mRNA, leading to the synthesis of the immunogen protein. If the transfected cell is a professional antigen-presenting cell (APC) (e.g. a dendritic cell) that expresses class I and II MHC proteins, as well as costimulatory molecules, the process of antibody production can proceed (Lai and Bennett 1998). The DNA vaccine effectively induces antibodies as well as cytotoxic T lymphocytes. Thus both humoral and cell mediated responses are induced – a distinct advantage. Barry et al. (1995) prepared an *M. pulmonis* library by fusing digested mycoplasmal DNA on to the last exon of the gene encoding the human growth hormone (hGH), using cytomegalovirus as a vector, so that hGH-*M.pulmonis* antigens might be secreted. Theoretically, a library expressing the entire genome of a pathogen could be used as a vaccine. Barry et al. (1995) found that about 1 ng DNA injected into the skin was required to produce an immune response. Mice immunized with *M. pulmonis* libraries and challenged had no culturable mycoplasmas and no lung lesions.

Lai et al. (1994) constructed an *M. pulmonis* genomic library cloned in λgt 11 and transfected into *E. coli*. Clones of *E. coli* expressing a fusion protein reactive with anti-*M. pulmonis* antibodies were transferred orally or intravenously into mice. Expression of fusion proteins in the mice was induced by adding isopropyl-β-D-thiogalactopyranoside (IPTG) into the drinking water, resulting in local and systemic antibody production and effective protection of the animals against large numbers of virulent *M. pulmonis*. DNA vaccines could also be used to treat animals already infected with *M. pulmonis*. When infected mice were immunized with the DNA vaccine 1 week after infection, the numbers of organisms recovered from tracheolung lavage gradually decreased and were totally eliminated by 4 months (Lai et al. 1997).

It is possible to select the epitope important as an immunogen, by isolating the dominant antigen, prepare

a mAb to it, and use this antibody to select the *E. coli* clone producing the specific fusion protein carrying this epitope. Thus, the DNA vaccine is controllable. Such a specific DNA vaccine was developed for *M. hyopneumoniae*. Following screening of the mycoplasmal clone bank with hyperimmune pig serum, Fagan et al. (1996) identified a clone with a sequence homology to the R2 subunit of ribonucleotide reductase. This clone was expressed in *E. coli* as an 11 kDa protein fused to β-galactosidase. Assessment of the vaccine potential of the fusion protein in pig trials showed the vaccinated pigs to be significantly protected against challenge with a virulent *M. hyopneumoniae*. Use of an attenuated *Salmonella typhimurium aroA* strain as a vector for delivery of the above immunogenic *M. hyopneumoniae* fusion protein did protect mice against experimental infection with *M. hyopneumoniae*, and thus has the potential of providing a cheap and easily administratable oral vaccine for swine (Fagan et al. 1997). Efforts to develop an effective DNA vaccine against *M. hyopneumoniae* are still under way, suggesting the failure of the above-described DNA vaccines to provide satisfactory protection of swine in field trials. A recent trial is that reported by Chen et al. (2003). They constructed a plasmid vector carrying the P42 heat shock protein gene of *M. hyopneumoniae* driven by the potent cytomegalovirus promoter. Injection of the plasmid into mice induced both humoral and cellular responses. The antiserum from the immunized mice inhibited growth of *M. hyopneumoniae*. One can only hope that this vaccine will offer better protection for swine than the previous DNA vaccines.

A novel genetic strategy to control phytoplasma diseases has been based on expression in plants of antibodies (plantibodies) that are able to interfere with multiplication of the pathogen. Le Gall et al. (1998) engineered a gene of a single-chain variable fragment antibody to a major membrane protein of the stolbur phytoplasma. They cloned it in a plasmid of *Agrobacterium tumefaciens* and transformed it to tobacco plants. The transformed plant carried the transgene. When grafted on a stolbur-infected tobacco root stock, the transgenic tobacco shoots grew free of symptoms, while normal tobacco shoots showed severe stolbur symptoms.

There can be little doubt of the great potential of DNA vaccines so that one may expect the rapid development of these new generation vaccines. Whether the high hopes will be substantiated will have to await the results of large-scale field trials.

DIAGNOSIS OF INFECTIONS

Mycoplasma identification and laboratory diagnosis of mycoplasmal infections has been based on the classical bacteriological tests, including morphology, cultural characteristics, physiological, and serological properties. While these tests still occupy a major part in mycoplasma diagnostics, new tests based on the molecular analysis of genomic DNA, ribosomal RNAs, cell proteins, and lipids appear to push aside the classical tests, and one may expect that the molecular tests will shortly become the prevailing tests in mycoplasma identification (Razin 2002). Systematic and detailed description and evaluation of the classical procedures used in mycoplasma identification can be found in the two volumes of *Methods in mycoplasmology* (Razin and Tully 1983; Tully and Razin 1983), while the newer molecular methods are included in the two more recent volumes of *Molecular and diagnostic procedures in mycoplasmology* (Razin and Tully 1995; Tully and Razin 1996). A succinct practical review of current methods applied in routine laboratory diagnosis of mycoplasmal infections, with emphasis on infections in humans, has been published (Waites et al. 2001).

Cultural properties and biochemical tests

The International Committee on the Taxonomy of Mollicutes issued recommended tests for mycoplasma identification, as well as for description of new species of the class Mollicutes (International Committee 1995). The recommended tests include those required to define a new isolate at the higher taxonomic levels (class, order, family), as well as tests for genus and species determination. Thus, a test for sterol requirement, based on growth promotion by cholesterol in the presence of either 0.01 or 0.04 percent Tween 80 (Tully 1995) separates the sterol-nonrequiring *Acholeplasma* and *Mesoplasma* species from the members of Mollicutes requiring cholesterol for growth. Other key tests to identify *Mycoplasma* and *Ureaplasma* species include those for sugar fermentation, arginine, and urea hydrolysis (Razin and Tully 1983).

Serological tests

A wide variety of serological tests have been employed, particularly in mycoplasma species and strain identification. The classical recommended tests include growth and metabolism inhibition by specific antisera, as well as direct and indirect immunofluorescence tests applied to mycoplasma colonies. A combined deformation-metabolism inhibition test system has been used to provide both screening and refined analysis and definition of *Spiroplasma* species (see the relevant chapters in *Methods in mycoplasmology*; Tully and Razin 1983). A variety of other, in some cases more sensitive, tests based on principles of enzyme-linked immunosorbent assay (ELISA), immunobinding, immunoblotting, immunofluorescence, and immunoperoxidase tests have been applied to mycoplasma diagnosis (see section B in Tully and Razin 1996).

A wide variety of serological procedures are based on detection of specific antibodies in sera of humans and animals suffering from mycoplasma infections. The procedures, as well as the evaluation of the results, are discussed in detail in the relevant chapters of *Molecular and diagnostic procedures in mycoplasmology* (Tully and Razin 1996) and in Waites et al. (2001). Serodiagnosis consists of examining serum samples for antibodies that inhibit the growth and metabolism of the organism or fix complement with mycoplasmal antigens. Being the best established and important human pathogen thus far, laboratory diagnosis of *M. pneumoniae* infections has been the subject of numerous studies (reviewed in Daxboeck et al. 2003). Antibody response in mycoplasmal pneumonia is most easily demonstrated by complement fixation (CF), reacting acute- and convalescent-phase sera with intact organisms or their lipid extract as antigen. A four-fold or greater antibody rise is considered indicative of recent infection (Ferwerda et al. 2001), whereas a sustained high antibody titer may not be significant, because a relatively high level of antibody may persist for at least 1 year after infection.

In view of the many limitations of CF tests, they have recently been largely replaced by methods applying alternative technologies, based mostly on enzyme immunoassays (EIA). Efforts were also invested in developing more defined and specific antigens based on immunodominant *M. pneumoniae* membrane proteins, such as P1 (Tuuminen et al. 2001) or the 116 kDa protein (Duffy et al. 1999). A P1-enriched antigen preparation was not only the most sensitive in detecting antibodies at the early stage of infection, but also detected antibodies to *M. pneumoniae* produced during the convalescent phase of infection (Tuuminen et al. 2001). This antigen is suitable for IgG, IgM, and IgA EIA testing (Suni et al. 2001). A combination of *M. pneumoniae*-specific PCR in nasopharyngeal aspirates with an IgM-capture immunoassay in acute phase sera, increases the sensitivity of rapid laboratory diagnosis of *M. pneumoniae*, enabling the attainment of a laboratory result in only 1 or 2 days (Ferwerda et al. 2001).

A variety of rapid tests based on indirect hemagglutination of erythrocytes or latex particles coated with *M. pneumoniae* antigens, or an immunofluorescence assay detecting IgM antibodies to *M. pneumoniae* (Dorigo-Zetsma et al. 1999) have been developed, and some are commercially available. EIA test kits presently achieve the largest market share of commercial mycoplasma serologic tests (Suni et al. 2001; Tuuminen et al. 2001; Waites et al. 2001). In summation, although PCR considerably extends the arsenal of reliable laboratory techniques, serology still retains importance in diagnosis of *M. pneumoniae* infections and of complications associated with *M. pneumoniae* infections. It is well known that IgM antibodies are frequently diagnostic in children because they are most likely experiencing an episode of a primary disease. In adults, on the contrary, IgM antibodies alone may not be diagnostic. Serology using IgA and IgA-antibody detection remains a method of choice for the diagnosis of acute infection in adults (Watkins-Riedel et al. 2001).

Restriction endonuclease analysis

The classic tests for mycoplasma identification and classification have been supplemented by a variety of tests based on genomic DNA analysis. Restriction endonuclease analysis (REA) of the mycoplasma genome provides a convenient and cost-effective means of determining DNA sequence variations among strains of mollicutes species (Razin and Yogev 1995). Variations in the array of fragments generated by a specific restriction endonuclease are called restriction fragment length polymorphisms (RFLP). RFLPs can result from sequence rearrangements, insertion or deletion of DNA segments, or base substitutions within the restriction endonuclease cleavage sites. Restriction endonuclease analysis has become a most useful taxonomic tool, facilitating the identification and classification of mycoplasmal isolates, as well as providing means for evaluating the degree of genotypic heterogeneity of strains within established species (Djordjevic et al. 2001; Razin 1992).

The great advantage of chromosomal restriction endonuclease analysis is that it is universally applicable and sensitive, because the entire genome is evaluated for RFLP, and in addition it is relatively easy to perform. Moreover, unlike SDS-PAGE of mycoplasmal cell proteins, restriction endonuclease analysis is not susceptible to contamination by culture medium contaminants, and requires very little (3–5 μg) of unlabeled DNA per test (Razin and Yogev 1995). A more recently developed technique, named amplified-fragment length polymorphism (AFLP) is a whole genome fingerprinting method based on the selective amplification of restriction fragments. This multistep procedure combines in an elegant manner the power of PCR with the informativeness of REA. AFLP yields more complex banding patterns than other DNA fingerprinting methods, increasing the discrimination between strains. In this way AFLP can be used as a device in studies of epidemiology, pathogenicity, and genetic variability in natural populations of mollicute species (Koktovic et al. 1999).

Southern blot analysis of genomic DNA digested by a restriction enzyme and hybridized with a cloned conserved gene or a specific genomic fragment as a probe, has become a most useful tool in the identification, classification and subtyping of mollicute species (Razin 1992; Yogev and Razin 1995). The fact that the rRNA operons in the various mollicutes differ in restriction sites within the operon and in the flanking sequences results in the production of hybridization patterns specific to different mollicute species or strains.

A restriction enzyme having a 6-bp recognition site will usually cut the one or two mycoplasmal rRNA operons in a few sites, so that the hybridization patterns are usually simple and much easier to compare than the multiband restriction patterns obtained by restriction endonuclease analysis of entire genomic DNA. Southern blot hybridization with cloned rRNA genes as probes has been named 'ribotyping'. However, other conserved genes can be employed as probes, such as the *tuf* gene, encoding the elongation factor EF-Tu. The mollicute genome carries only one copy of this gene, so that the hybridization patterns obtained with restricted mollicute DNAs are also very simple and easy to compare (Razin 1992).

PCR-based diagnostic procedures

The introduction of PCR to diagnostics in the late 1980s pushed aside many of the previously developed DNA probes and commercial kits (Razin 1994). PCR tests are several orders of magnitude more sensitive than those based on direct hybridization with a DNA probe. Moreover, PCR is fast, copying a single DNA sequence over a billion times within 3 hours. Nucleic acid amplification techniques are not limited by the ability of an organism to grow in culture, a feature of paramount importance considering the fastidious nature of some mycoplasmas, such as *M. genitalium*, and the fact that not all mollicutes can be cultured in vitro, notably the phytoplasmas, and the hemoplasmas (*Eperythrozoon* and *Haemobartonella* species, see Phylogeny and taxonomy section). Thus, PCR-amplified 16S rDNA subjected to RFLP analysis has become the method of choice for routine detection, differentiation, and classification of phytoplasmas (Marcone et al. 2000; Seemuller et al. 2002).

PCR methodology is still at a phase of rapid development and new procedures, modifications, etc., are reported almost daily. Detailed descriptions of methodology and evaluation of PCR-based tests in diagnostics can be found in the relevant chapters in *Molecular and diagnostic procedures in mycoplasmology* (Tully and Razin 1996). The first major step in the development of a PCR-based test concerns the selection of the appropriate target sequences for amplification. The sequence to be amplified can be chosen from a published mycoplasmal gene sequence or from a randomly cloned DNA fragment demonstrated to be specific for the mycoplasma to be detected (Kong et al. 2001; Caron et al. 2000). Complete or almost complete sequences of the 16S rRNA genes are now available for almost all the established mollicute species, and can be retrieved from data banks (see Phylogeny and taxonomy section). This facilitates the selection of a variety of target sequences, starting with sequences in the highly conserved regions of the genes, producing primers of wide specificity ('universal primers') which will react with the DNA of any mycoplasma or even with the DNA of other prokaryotes. These may be satisfactory for detection of mycoplasma infection in cell cultures, where the goal is just to screen the cultures for contamination. In case of a need to differentiate the contaminating mycoplasmas, a multiplex PCR system can be employed, consisting of a universal set of primers along with primer sets specific for the mycoplasma species commonly infecting cell cultures (Choppa et al. 1998; Kong et al. 2001). The mycoplasmal 16S rRNA genes carry, in addition to the conserved regions, more specific variable regions, as well as specific 16S–23S intergenic spacer regions. Primers can be selected from these regions with various degrees of specificity, ranging from clusters of species, single species, down to the subspecies level (Kong et al. 2001).

Although conventional PCR tests should, under optimal conditions, detect the DNA of a single mycoplasma, this rarely happens in testing clinical material. Two-step (nested) PCR has been devised to increase sensitivity to a level enabling detection of a single mycoplasma in a clinical sample (Verdin et al. 2000). Another advantage of nested PCR is that the second round PCR serves to confirm the specificity of the first round PCR. Another approach is that termed random amplified polymorphic DNA (RAPD), or arbitrary primer PCR (AP-PCR). It involves PCR amplification with a single arbitrary primer at low stringency, resulting in strain-specific arrays of DNA fragments that can reproducibly distinguish even closely related strains of a species. The simplicity of this procedure, and the availability of commercial kits should facilitate the use of RAPD analysis as a routine procedure for identification of strains of a mollicute species, employing the RAPD patterns to investigate disease outbreaks for epidemiologic tracking (Cousin-Allery et al. 2000).

Comparing PCR results with those of culture and serology

Numerous publications compare the results of the PCR technique with culture and serological testing for *M. pneumoniae* (for references see Razin 2002 and Daxboeck et al. 2003). Most publications indicate the higher sensitivity and the much faster results obtained by PCR (for examples, see Dorigo-Zetsma et al. 1999 and Ferwerda et al. 2001). The sensitivity of PCR assays is usually in the order of magnitude of a few femtograms of mycoplasmal DNA. When translated into numbers of organisms, 1 fg of mycoplasmal DNA is approximately equivalent to the genomic DNA of a single mycoplasma cell, based on a genome size of about 1 000 kb. The ability to detect by PCR a single mycoplasma cell makes PCR the most sensitive detection method available, even more than culture. In theory, a positive culture can

be derived from a single mycoplasma cell. In practice, however, due to many reasons (including mycoplasma cell aggregates, multinuclear filamentous forms, defective or nonviable cells) a positive mycoplasma culture requires an inoculum equivalent to about 100 to 1 000 cells. This is known for other bacteria as well and is the reason for using the expression colony-forming units (cfu) or color-changing units (ccu) rather than number of cells per milliliter (Razin 1994).

Obviously, PCR should be applied in the case of patients with an impaired immune response where serological tests may be much less effective. Positive PCR results for *M. pneumoniae* in culture-negative persons without evidence of respiratory disease suggests either inadequate specificity of the test, persistence of the organisms after infection, or their existence in asymptomatic carriers, making interpretation of such results difficult (Waites et al. 2001). In other words, would such a sensitive technique as PCR lead to 'over-diagnosis' of *M. pneumoniae* infections partly due to its detection in healthy carriers? It is still difficult to answer this question in a definitive manner.

In conclusion, PCR detection of mycoplasmas is still too labor-intensive, expensive, and complex to be carried out routinely in most clinical microbiology laboratories. Development of satisfactory commercial PCR kits may simplify the procedures and bring about better standardization of the technique, and if available at a reasonable cost, PCR could become the major method for diagnosis of mycoplasmal infections.

HISTORIC PERSPECTIVES

The first means to diagnose infections by chlamydia (i.e. by *Chlamydia trachomatis*) was the demonstration of intracytoplasmatic inclusions in smears of eye secretion in cases of 'inclusion conjunctivitis,' a discovery made at the beginning of the twentieth century (Halberstaeter and von Prowasek 1907). During this period it was also demonstrated that parents to babies suffering from this condition also had genital mucosal cells with similar inclusions. The designation of *C. trachomatis* refers to its etiological role in trachoma (Darougar and Jones 1983). Since then, lymphogranuloma venereum (LGV) is also known as a chlamydia infection. A 'rediscovery' of *C. trachomatis* as one of the main causes of nongonococcal urethritis (Dunlop et al. 1972) and cervicitis (Brunham et al. 1984) was made during the 1970s and early 1980s. Complications thereof, such as endometritis and salpingitis (pelvic inflammatory disease (PID)), could be linked to infection by *C. trachomatis* (Mårdh et al. 1977). It was also demonstrated that newborns could develop not only conjunctivitis (Stenberg and Mårdh 1990), but also pneumonia (Beem and Saxon 1977).

During the 1930s, Bedson described the life cycle of chlamydia (i.e. of *Chlamydia psittaci*) (Bedson et al. 1930). The organisms were for some time named Bedsonia after him. It was established that 'parrot fever' or psittacosis/ornithosis was caused by *Chlamydia psittaci*. The agent could be associated with a variety of animals infections and with zoonotic infections, such as abortion and premature birth in women infected by sheep (Johnson et al. 1985), and conjunctivitis due to the feline conjunctivitis agent (Hartley et al. 2001).

In 1976, respiratory tract infections occurred in a Finnish military camp (Kleemola et al. 1988). Isolated agents had similarities to chlamydia strains recovered from the eyes of persons in Taiwan (strain TW-183) and Iran (strain IOL-207) and from a case with acute respiratory tract infection in the USA (strain AR-39). They were regarded variants of agents classified as *C. psittaci*. Initially, these agents were recognized as the TWAR agents (Kuo et al. 1986), now recognized as a separate species, i.e. *C. pneumoniae*. Seroepidemiological studies showed that antibodies to these agents occur more often in persons who later developed heart infarction (Saikku et al. 1988). This observation led to investigations into whether or not there is a correlation between arteriosclerosis and *C. pneumoniae* (Kuo et al. 1993; Campbell and Kuo 2003). If an association, or even correlation, really exists is, however, still an open matter (van der Ven et al. 2002; Broman and Hammerschlag 2002).

In 1957, embryonic hen eggs were used to isolate *C. trachomatis* (T'ang et al. 1957). This latter method was, however, not suitable for routine clinical use, which is why the introduction of tissue cell cultures in 1965 meant a step forward (Gordon and Quan 1965). Later developments involved the use of HeLa 229 cells treated

with DEAE, i.e. a dextran of high molecular weight. Other pretreatments utilized emetin, cytochlasin B, hydrocortisone or iodoxyuridine (IUDR). Irradiation of the cells increased their sensitivity to infection. The need to prepare the cells by irradiation and/or chemicals some days before use meant great restrictions if diagnostic services were to be applied on a large scale. In 1976, a diagnostic breakthrough was made by application of cycloheximide treatment of McCoy cells. This could be made in conjunction with infection of the cells, which made it practical and cheap to use cell cultures (Ripa and Mårdh 1977). By application of this method, screening studies could demonstrate the wide spread of genital chlamydial infections in general populations. Enzyme-linked immunosorbent assay (ELISA), e.g. Chlamydiazyme®, was widely applied in the diagnosis of genital infections by *C. trachomatis* until the end of the 1990s, when nucleic acid-based tests took over in many laboratories. In retrospect, the use of ELISA tests can be regarded as 'the dark age' in chlamydial diagnostic services, as their sensitivity was low, i.e. 50–70 percent. In comparison, adequately performed cell cultures have a sensitivity of at least 85 percent. During the 1990s, kits with amplified nucleic acid tests, such as polymerase chain reaction (PCR) (Livengood and Wrem 2001) and ligase chain reaction (LCR) (Lee et al. 1995) came on the market.

TAXONOMY

The species of the genus *Chlamydia* are shown in Table 1. Three species occur in humans, i.e. *C. trachomatis*, *C. psittaci*, and *C. pneumoniae*. The fourth species of genus *Chlamydia,* i.e. *C. pecorum*, is a nonhuman pathogen. The chlamydia organisms belong to the family Chlamydiaceae in order Chlamydiales. On the basis of molecular markers, a new taxonomy for chlamydia organism has been proposed, using the denomination *Chlamydophila* for genus (Everett et al. 1999). These authors proposed the recognition of *C. muridarum* and *C. suis*. However, this taxonomy has not been generally accepted and was opposed by a large group of researchers in the field (Schachter et al. 2001). The old taxonomy is used in this chapter.

C. trachomatis was initially divided into 15 serovars (Table 1). More recently, the proposal of four new subtypes of earlier recognized serovars have been made, i.e. Da, Ga, Ia, and L2a. Serovars of *C. trachomatis* have been identified by microimmunofluorescence (MIF) tests (Wang and Grayston 1982). The subidivision by MIF fitted well with the clinical spectrum of infections caused by the various serovars and with subdivision obtained by genetic sequencing. Differences in the major outer membrane proteins (MOMP) can form a base for subdivision of *C. trachomatis* into different serovars (Caldwell and Schachter 1982). Using antibodies raised against different domains of MOMP, such subdivisions can also be made. PCR-based restriction fragment length polymorphism of outer membrane protein (OMP) 1 means a simpler method for serovar typing than by MIF tests (Frost et al. 1991).

Chlamydia pneumoniae was initially included in *C. psittaci* (Kuo et al. 1986). Structural and antigenic analyses formed the base for separating *C. pneumoniae* into its own species (Campbell et al. 1990).

REPRODUCTIVE CYCLE

Chlamydia organisms, which are intracellular parasites, multiply by binary fission in a cytoplasmatic vacuole which is surrounded by a membrane with similarities to the host cell's cytoplasma membrane (Conati et al. 2002). Chlamydiae are classified as bacteria, but have a unique mode of replication as illustrated in Figure 1.

The infectious particle is the elementary body (EB) (Figure 2). The EB adheres to the host cell with the aid of heparin-sulfate-like glucosaminoglycan molecules which are required for chlamydia to enter a host cell. A number of substances are known to enhance contact between EBs and host cells, i.e. diethylaminoethyl-dextran and iodoxyuridine, which have been utilized in in vitro cultures. The EB is taken up through a vesicle, a phagosome, without phagolysosomal fusion. After an eclipse phase of approximately 12 h, the EB develops into a reticulate body (RB). The EB has a diameter of 200–300 nm, whilst that of the RB is 1 000–1 500 nm. The RB is divided by binary fission inside the vesicle. During the synthesis of substances by the chlamydia cell, the metabolism of the host cell is depressed through influence of the chlamydia parasite. Eighteen to 24 h after the EB has attached, the RBs are undergoing reorganization into EBs. Within another 6 h, the EBs are

Table 1 *Taxonomy of the chlamydia organisms*

Taxonomy

released and the host cell dies. In vivo, the developmental cycle is longer than in in vitro cultures. Its exact time may differ by prevailing circumstances but may be up to a week. At the end of the reproductive phase, the chlamydia inclusion may be so large that it displaces the nucleus of the host cell. This phenomenon may give the impression that the inclusion more or less surrounds the nucleus, like an overcoat. This once gave the organisms their name 'chlamydia,' which in Greek means 'overcoat.'

BIO- AND IMMUNOCHEMISTRY GENETICS

Most bio-, immunochemical and genetic data on chlamydia organisms are derived from studies of *C. trachomatis*. Handling of *C. psittaci* involves risks for laboratory infections and *C. pneumoniae* is difficult to culture.

The chlamydia organisms are energy parasites of eukaryotic cells, which supplies them with ATP, GTP, and UTP. The metabolism of the chlamydia organisms is, otherwise, similar to that of eubacteria (Mårdh et al. 1989).

The EB has a central, electron dense area surrounded by a cytoplasmatic membrane and a double-layered

outer membrane. The outer membrane is made up of up to 50 percent protein and 30 percent lipids as well as fatty acids and carbohydrates (Birkelund et al. 1989; Siridewa et al. 1993; Su et al. 1996; Yxfeldt et al. 1994; Kuo et al. 1996; Stephens et al. 2001; Conati et al. 2002). The EB has a lipopolysaccharide (LPS) surface structure, which is common to all species of the genus *Chlamydia.* The LPS has two antigenic domains. One is shared with gram-negative bacteria while the other is specific for chlamydia organisms. LPS contains a genus specific epitope, i.e. 3-deoxy-D-manno-oct-2-ulopyranosonic acid (KDO). This trisaccharide is highly antigenic. The chlamydial cell wall also contains proteins, e.g. the MOMP, which has a molecular weight of 40×10^6. The MOMP has four variable domains (I, II, III, and IV). Differences between them can be utilized to identify the various species of genus *Chlamydia* (Zhong et al. 1990). Apart from MOMP, there are other proteins on the cell surface, i.e. Omc A and Omc B.

The guanine + cytosine (G + C) content of the DNA of *C. trachomatis* is 44 percent and that of *C. psittaci*/*C. pneumoniae* is 41 percent. The DNA homology is only 10 percent between the two species, while the 16S RNA gene sequence shows over 95 percent homology. The genome of *C. trachomatis* is a double-stranded DNA molecule with a molecular weight of 660×10^6. The entire 1000 kb genome of *C. trachomatis* has been sequenced (Stephens et al. 2002). The structure of MOMP and the sequence of the MOMP genes of *C. psittaci* have been studied (Zhang et al. 1989).

Almost all strains of *C. trachomatis* tested contain additional genetic material in the form of a 7.5 kb cryptic plasmid (Peterson et al. 1990). The nucleic acid sequence is used for diagnostic purposes in PCR and LCR tests (see the section on Diagnosis below). Although only single strains have so far been detected that do not carry this plasmid, individuals harboring such strains will therefore remain undetected in such tests. Obviously, a more general check for the presence of nonplasmid-containing strains of *C. trachomatis* is essential, as long as the main diagnostic tools are based on the nucleic acid sequence in the cryptic plasmids.

PATHOGENESIS AND IMMUNE RESPONSE

Apart from being an intracellular parasite causing cell disruption and death of the host cell (Conati et al. 2002), the pathogenicity mechanisms of chlamydia organisms are not well understood. However, a cytotoxin has been recognized. The LGV serovars are more invasive than the non-LGV serovars, causing ulceration and lymphangitis. The other serovars of *C. trachomatis* (Table 1) cause infection of epithelial linings, such as of the mucosa of the cervical channel, endometrium, uterine tubes, urethra, vas deferens, epididymis, and conjunctiva. Tumor necrosis factor (TNF)-α-induced physiological apoptosis can be inhibited by a chlamydial infection (Fan et al. 1998).

A chlamydial infection may result in proinflammatory cytokine production, along with an immune response to the agent and induce antibodies to heat shock proteins (hsp), e.g. to hsp60 (Witkin et al. 1996). As chlamydia and other bacteria share epitopes with human hsps, it has been speculated that chlamydial infections may cause an autoimmune response. hsp60 production can cause localized inflammatory reactions, e.g. in the uterine tubes. RBs may escape the immune response and thereby explain persistent infections. Formation of new EBs from RBs can induce an immune response and inflammatory reactions resulting in a cyclic process of scarring of the infected tissue. For example, this may eventually lead to partial or total obliteration of the fallopian tubes causing tubal factor infertility or subinfertility. If the vas deferens is affected, the male may transiently be subfertile. Such a pathogenicity mechanism might also explain the lower success rate of in vitro fertilization in women with evidence of a passed genital chlamydial infection. In trachoma, immune reactions contribute to changes resulting in blindness.

Clearance of a chlamydial infection and resistance to reinfection is dependent on T-cell response. CD4- and CD8-positive cells are engaged. Interferon-γ may inhibit multiplication of RBs.

C. pneumoniae can prevent programmed cell death in experimentally infected cell cultures (Carratelli et al. 2002), claimed as a possible pathogenicity principle. A role of chlamydial hps60 in stimulation of an innate immune response to *C. pneumoniae* has been demonstrated (Costa et al. 2002).

CHLAMYDIA TRACHOMATIS

Epidemiology

The World Health Organization (WHO) has estimated that the number of new genital infections by chlamydia has almost reached 100 million annually, which makes these infections one of the most prevalent sexually transmitted diseases (STD). However, the epidemiological situation varies by country (Norman 2002). This can partly be explained by the introduction of national screening programs (Mårdh 2002b). Where such measures have been undertaken, the prevalence of genital chlamydial infections has markedly decreased and so have their complications, e.g. PID (Weström 1998). In the UK, a recent increase in the prevalence of such infections has been seen, whereas in the Scandinavian countries there has been a decrease, although a small increase has been noted in recent years (to some extent due to the introduction of nucleic acid detection methods). It should, however, be observed that population-based data and reliable surveillance systems are

generally lacking (Mårdh 1998). The number of cases detected closely depends on whether screening for chlamydia carriers is performed, as the majority of those who are infected by *C. trachomatis* are more or less asymptomatic and have no reason to consult health providers. The number of genital chlamydial infections detected in a region or country is also dependent on whether or not partner notification is performed (Mårdh 1998). Access to diagnostic services and knowledge of which detection methods are in current use is essential. Some currently used methods have a low sensitivity and/or specificity. This means that either a large proportion of cases remain undetected or are being falsely reported as chlamydia-infected. To sum up, epidemiological data based on population surveys are almost nonexistent and surveillance data must be interpreted with caution.

Young age is identified as a risk factor to contract genital chlamydial infections and also for reinfection (Norman 2002). Thus, in most societies, young teenagers belong to those that should be addressed in preventative work, which has to start at school age to be effective (Mårdh 2002b). With the knowledge that young adults are most commonly infected, screening of middle-aged persons is often neglected. Therefore, the age distribution of documented cases can be misleading for understanding the chlamydia epidemic situation. As for other STDs, a high number of sex partners is, of course, also a risk factor. The transmission rate of genital chlamydial infections is, however, poorly documented.

Trachoma is regarded as the most common cause of preventable blindness (Darougar and Jones 1983). Some decades ago, it was estimated to affect some hundred millions of persons. The so-called 'trachoma belt' covers North Africa and the Sub-Saharan region, Middle East, the dry area of the Indian subcontinent, and South East Asia. Recent society developments and trachoma prevention programs have markedly reduced the prevalence of trachoma (Jones 1975). Ethnic belonging, rather than poor sanitary conditions, seems to play a role for the prevalence of trachoma in displaced persons living in the same camp (Mahmoud et al. 1994a).

Table 2 *Conditions in nonpregnant and pregnant women, in fetuses, in newborns, and in males, in whom infections with* Chlamydia trachomatis *plays an etiological role. Sequelae of these conditions are also listed*

Manifestations	Sequelae
Nonpregnant women	
Cervicitis	Infertility
Endometritis	Chronic abdominal pain
Salpingitis	Ectopic pregnancy
PID	Chronic obstructive lung disease
Periappendicitis	Asthma
Perihepatitis/peritonitis/perisigmoiditis	Trachoma (entropion, pannus, blindness)
Fetus	
Chorioamnionitis ?	
Intrauterine infection of fetuses	
Postpartum PID	
Newborns	
Conjunctivitis in newborns	
Pneumonia in infants	
Males	
Uretritis

Vaseitis	
Both genders	
Proctitis	
Sexually acquired reactive arthritis (SARA)	
Reiter's syndrome	

Clinical syndromes

The manifestations of infections by *C. trachomatis* are shown in Table 2.

GENITAL INFECTIONS IN NONPREGNANT FEMALES, INCLUDING CERVICITIS, ENDOMETRITIS, AND SALPINGITIS (PID)

Chlamydia infections may involve both the lower and upper genital tract of men and women (Mårdh et al. 1977, 1981a; Holmes et al. 1980; Svensson et al. 1981; Ingerslev et al. 1982). In most countries today, *C. trachomatis* is the most common cause of cervicitis. The columnar epithelium of the cervical channel is infected. Mucopurulent discharge from the cervical os is a characteristic finding (Brunham et al. 1984). The majority of chlamydial cervicitis cases is low-symptomatic. Cervical ectopy is not related to an increased risk of contracting chlamydial infection. Tubal infections may spread through the fallopian tubes to intraabdominal sites, such as to the liver surface (Wölner-Hanssen et al. 1981; Mårdh and Wölner-Hanssen 1985).

C. trachomatis is a common etiological agent of endometritis (Mårdh et al. 1981a). Chlamydial endometritis (and salpingitis) is associated with production of chlamydial hsp60 antibodies (Peeling et al. 1997) which elicit a mononuclear cell reaction. An intensive mononuclear cell infiltration can be seen in endometrial aspirates after specific histological staining (Figure 3). Approximately 40 percent of all women with genital chlamydial infections have a PID. In clinical practice it is not possible to determine which patients do have an ascending infection. The infection may spread to the tubes and cause salpingitis (Mårdh et al. 1977; Svensson et al. 1981) (Figure 4). The latter infection may spread further to the abdominal cavity to cause periappendicitis, peritonitis, perihepatitis, perisplenitis, and perisigmoiditis (Wölner-Hanssen et al. 1981; Mårdh and

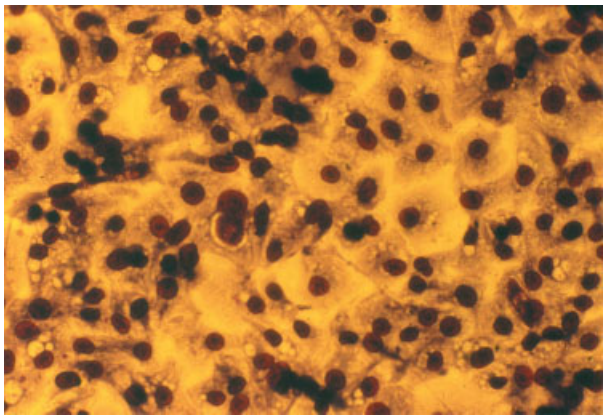

Figure 3 *Chlamydial endometritis with a characteristic plasma cell infiltration*

Wölner-Hanssen 1985) (Figure 5). In chlamydial perihepatitis, the affected woman may present with pain under the right arcus, which can mimic a cholecystitis attack. Tubal infections may result in tubal factor infertility (Henry-Suchet et al. 1981; Svensson et al. 1983; Patton et al. 1994). This risk increases with each episode of salpingitis. In rough terms, the risk for involuntary childlessness is 25, 50, and 75 percent after one, two, and three episodes of PID, respectively. A repeated episode of salpingitis may not necessarily be due to chlamydial infection, but to bacterial infections in a damaged tube. Extrauterine pregnancy (Svensson et al. 1985) is associated with a past chlamydial infection. Chronic abdominal pain may be still another sequelae of PID due to *C. trachomatis*.

Oral contraceptives can influence the natural history of genital chlamydial infections (Svensson et al. 1984) and mask symptoms of chlamydial PID (Mårdh and Hogg 1998). In women with chlamydial salpingitis who are on the pill, spread of the infection into the abdominal cavity is less common than in nonusers.

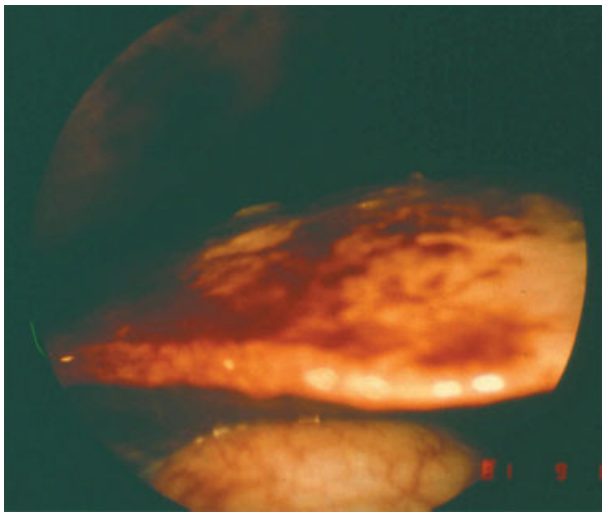

Figure 5 *Chlamydial perihepatitis in a case of chlamydial salpingitis showing the characteristic fibrin deposit on the liver capsule*

NONGONOCOCCAL AND POSTGONOCOCCAL URETHRITIS

The term nongonoccocal urethritis (NGU) was coined to characterize cases of urethral discharge that could not be associated with gonorrhea (Dunlop et al. 1972). When methods to diagnose *C. trachomatis* infection had been established, the true etiology of these cases was discovered. By the end of the 1970s, NGU cases outnumbered those of gonococcal urethritis; a situation which has remained so in most countries. This is also true for urethritis that persists after microbiological, but no clinical cure, of gonorrhea, i.e. for postgonococcal urethritis (PGU). PGU is often due to an infection by *C. trachomatis* not cured by conventional gonorrhoea therapy.

ADVERSE PREGNANCY OUTCOMES

Chlamydial infections are of specific concern in pregnancy (Mårdh 2002a) (Table 2). Such infections have been associated with a number of adverse pregnancy outcomes, such as early and late abortion, stillbirth, prematurity, small-for-date babies, and intrauterine fetal infections. Serological evidence of an intrauterine infection by *C. trachomatis* was found in 10 percent of babies born preterm or in the case of stillbirth, as evidenced from tests of cord blood (Gencay et al. 2000). For any one of these conditions, it is difficult to assess the role, if any, of confounding factors such as genetic polymorphism for interleukine production.

Ectopic pregnancy correlates to a history of PID (Svensson et al. 1985; Brunham et al. 1986) and presense of hsp60 antibodies (Sziller et al. 1998). In countries where nationwide massive screening programs for detection of genital chlamydial infection have been performed, the rate of extrauterine pregnancies has decreased dramatically (Mårdh 2002a).

Infection by *C. trachomatis* may also interfere with in vitro fertilization (IVF) trials (Wölner-Hanssen and Mårdh 1984; Witkin et al. 1994). *C. trachomatis* can attach to, and even penetrate, spermatozoa. hsp60 antibodies to *C. trachomatis* are found in cases subjected to IVF (Spandorfer et al. 1999).

Elective abortion in cervical carriers of *C. trachomatis* involves an increased risk of developing post-abortion PID (Möller and Mårdh, 1980). Therefore, testing women to be subjected to legal abortion has been recommended as a routine measurement.

LGV

LGV is caused by serovars L 1–3 of *C. trachomatis*. LGV is usually found in tropical and subtropical countries (Perine and Stamm 1999). In other regions, it usually occurs as import cases. The incubation period is 1–3 weeks. The first sign of infection is usually a vesicle or an ulcer on the penis or on the fourcette in women (the latter easily gets undetected). Also, extragenital sites such as the fingers may be the primary location. As in syphilis, the ulcer heals. Later, there will be involvement of the inguinal lymph nodes, which occurs after 2–16 weeks. The lymph nodes get swollen, painful, and will suppurate, often through several sinuses. In one third, this phenomenon is seen bilaterally. This is the characteristic 'bubo' of LGV. If the lymphatic nodes under the inguinal ligament are involved, there is the so-called 'groove sign.' In women, the iliac lymphatic glandulae are commonly involved. This second stage of LGV is accompanied by constitutional symptoms, such as chills, headache, myalgias, and arthralgias. When the LGV organisms invade the lymphatic system, it may result in lymphstasis causing elephantiasis of the genital region. There could also be manifestations from several other organs, e.g. the eyes, central nervous system (CNS), heart, and lungs. Rectal strictures and development of rectal and rectal–vaginal fistulae may also be seen.

LGV should be included among differential diagnosis of any genital ulcer if there is any history or epidemiological data supporting the possibility of such an etiology. If case culture is used to diagnose LGV, the entire cell carpet will generally become infected, which can be used as a differential diagnostic marker for LGV. Detection of antibodies to chlamydia LPS has been used to diagnose LGV, as well as PCR and genetic referencing.

CONJUNCTIVITIS

Chlamydial conjunctivitis, also named paratrachoma and inclusion conjunctivitis (usually debuts unilaterally to spread to the contralateral side) is seen in newborns (Figure 6), infants, children, and adults (Figure 7) (Stenberg and Mårdh 1990). It affects the lower lid where follicules are found (Figure 8). It often debuts in the newborn after 1–2 weeks, but may do so within days if the baby has been infected in utero. Chlamydial

Figure 6 *Neonatal conjunctivitis caused by* Chlamydia trachomatis

conjunctivitis is seen in adults with a frequency of one to 200–400 reported cases of genital chlamydial infection. In newborns, the condition is generally self-healing. Credé prophylaxis is ineffective against *C. trachomatis*. The condition is often misdiagnosed and affected persons have often consulted several physicians before the diagnosis is established. Conjunctivitis in a newborn may indicate that the baby or infant also has concomitantly chlamydial pneumonia. It should be noted, however, that half of all neonatal chlamydial pneumonia cases lack signs of conjunctivitis. Chlamydial conjunctivitis resolves over 3 months without treatment. In adults, a concomitant genital chlamydial infection should be searched for (Stenberg and Mårdh 1993). Autoinoculation of the eye with genital secretion is believed to be the most common route of transmission of chlamydial conjunctivitis.

PROCTITIS, EPIDIDYMITIS, AND VASEITIS

C. trachomatis infection can be a cause of proctitis (Stamm et al. 1982). Epididymitis is one complication of chlamydial urethritis, which is most often seen in age groups in which infections with *C. trachomatis* are most

Figure 7 *Chlamydial conjunctivitis in a young man showing intensive congestion*

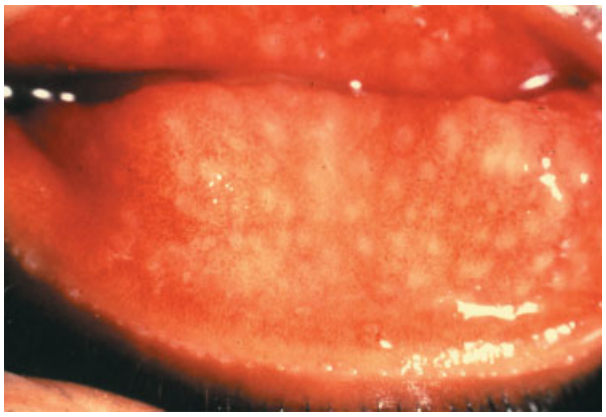

Figure 8 *Chlamydia follicles in the lower lid of a case of inclusion conjunctivitis*

common (Berger et al. 1978). The epididymitis is usually unilateral, which may explain why infertility in males on the basis of a past chlamydial infection is uncommon. It is, however, believed that it may cause transient subfertility. This may also be due to transient occlusion of vas deferens, which can be seen in grivit monkeys experimentally infected with *C. trachomatis* (Möller and Mårdh 1980).

ARTHRITIS AND UVEITIS

Chlamydial arthritis that occurs in conjunction with a genital infection is named sexually acquired reactive arthritis (SARA). Chlamydial urethritis is also one manifestation of nondysenteric Reiter's syndrome, i.e. arthritis, acute anterior uveitis (an intraocular inflammatory disease of the iris or ciliary body of the eye), and urethritis (Keat 1980). SARA is linked to histocompatibility antigen HLA-B27. Chlamydial antigen has been detected in synovial fluid, but whether the chlamydia organisms actually invade joints, and if so, if only transiently, has been discussed for decades. Seroepidemiological studies seem, however, to support an etiological role of *C. trachomatis* in some of these cases.

CERVICAL CANCER

A possible correlation between cervical cancer and genital chlamydia infections has been considered since the beginning of the 1980s (Schachter et al. 1982). Oncogenic types of human papilloma viruses, i.e. types 16/18, closely link the etiology of cervical cancer to infections. These types are involved in at least 90 percent of cervical cancer cases, while several of the other almost 100 HPV types may account for another 5 percent. In a serological study of more than 50 000 Scandinavian women (using sera collected many years previously) who were subjected to cytological screening, antichlamydial antibodies to serotypes G was significantly more common than in controls (OR 6.6 (1.6–27.0)), followed by serotypes I and D (Anttila et al. 2001). The study design did not, however, allow investigation of potential confounding factors such as smoking, sexual risk taking, including number of sex partners, and any difference between healed and nonhealed HPV infections.

NEONATAL INFECTIONS

There are two major manifestations of neonatal chlamydial infection, namely conjunctivitis (Stenberg and Mårdh 1990) and pneumonia (Beem and Saxon 1977), although the lower genital tract may also be colonized. It is believed that the infection is mainly spread from the mother to the infant when the fetus is passing through the birth canal (Schachter et al. 1986). A very early onset may indicate that the child was already infected in utero (Gencay et al. 2000), both in cases with and without premature rupture of the membranes (PROM). There is a comparatively higher chance for an infant to only become transiently colonized in the eyes than to develop clinical chlamydial conjunctivitis (Mårdh et al. 1980b).

Neonatal conjunctivitis often manifests mono-ocularily and the fellow-eye will become affected after 2–7 days in three-quarters of cases, which is earlier than in adults. The eyes of the infant with chlamydial conjunctivitis may be covered by copious discharge. There is usually edema and erythema of the eyelids (Figure 6). There may be bleeding when touching the conjunctival surfaces at examination or during sampling. The nasopharynx is colonized by *C. trachomatis* in one third of cases, which is believed to be the source of lung infections.

A neonatal chlamydial lung infection may easily be overlooked as symptoms are often only vague. The child becomes ill after approximately 6 weeks which is when the parents are likely to be the only observers of the infant's health. The child may be afebrile or only subfebrile. There may be a cough and congestion that the parents often will not recognize as pathologic. Lung auscultation may reveal rales and there may be tachypnea. Chest X-ray shows diffuse infiltrates and hyperinfiltration. Histologically, there are diffuse interstitial and alveolar infiltrates. The child may have eosinophilia (>300 mm^3) and the total serum concentration of IgM may be increased. The presence of antichlamydial IgM antibodies to *C. trachomatis* is a pathognomonic sign. It is notable that *C. trachomatis* pneumonia only occurs in newborns, while *C. pneumoniae* is responsible for chlamydial pneumonia in adults. Neonatal chlamydial pneumonia may involve the risk of developing chronic obstructive lung (COL) disease.

TRACHOMA

Trachoma has been the most common cause of preventable blindness (Darougar and Jones 1983; Jones 1975). The pathological changes in the eyes are more pronounced in the upper than the lower lid. This is in contrast to paratrachoma (inclusion conjunctivitis), where the situation is the opposite (Figure 8). There

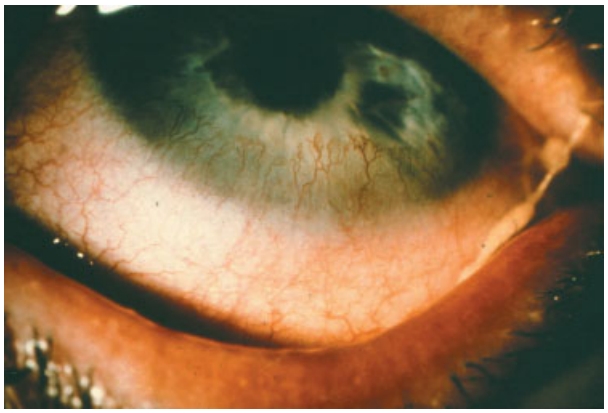

Figure 9 *Pannus formation in a case of trachoma*

are limbal follicules, pannus formation, and scarring, which very rarely occurs in paratrachoma cases (inclusion conjunctivitis). Trachoma may develop over decades and lead to blindness with pannus formation (Figure 9). Immunological, mechanical (entropion causes lesions of the cornea), and infections by other organisms which affect the injured eye makes the condition gradually progress. The prevalence of trachoma is related to poverty, overcrowded living conditions, and poor sanitation. Also, behavior factors may influence the prevalence (Mahmoud et al. 1994a).

CHLAMYDIA PSITTACI

Epidemiology

In the past there was an obvious overdiagnosis of human cases of infections with *C. psittaci* due to crossreactivity with *C. pneumoniae* (TWAR) or even with *C. trachomatis* if based on serology. Birds are the most common source of human infections ('parrot fever') (Olsen et al. 1998), although *C. psittaci* infects a large number of animals. Individuals shown by serological tests to be infected with *C. psittaci* refused to admit that they had had any recent contact with birds or any other animals. Interindividual transfer of infections by *C. psittaci* is a rare event. Spread from animals to humans may be airborne, but often occurs by handling infected material. Infected birds and other non-avian animal species may be healthy carriers of the organism. Persons most vulnerable to contract infections are those plucking and eviscerating birds in butchery plants, i.e. from chickens, turkeys, and ducks (Andrews et al. 1981). Feathers, excrement, nasal secretion, and viscera of infected birds can be the source of infection. Persons owning caged birds may occasionally be infected, as can veterinarians. Human infections have often been associated with the import of pscittacine birds, e.g. of budgerigars and cockatiels. As such birds may spread *C. psittaci*, many countries have strict quarantine regulations for importing caged birds. Other groups in danger of contracting infections are zoological shop personnel and persons connected to pigeon races. A famous epidemic occurred on the Faroe Isles among pickers of seagull eggs. The risk of laboratory infections must also be taken into account as a method of acquiring infections by *C. psittaci*, as must participation in the autopsies of infected animals.

Goats, sheep, pigs, horses, and cattle may be infected by *C. psittaci* (McCauly and Tieken 1968; Dilbeck et al. 1986). Humans are less often infected by these domestic animals.

Clinical conditions in humans

C. psittaci infections may spread from animals to humans, i.e. being the cause of zoonotic infections (Table 3).

PNEUMONIA AND EXTRAPULMONARY MANIFESTATIONS

Lung infections caused by psittacine birds have been referred to as cases of psittacosis, while infections by *C. psittaci* with nonpsittacine strains have been referred to as ornithosis cases.

The incubation period of psittacosis is 1–2 weeks to 1 month (Eidson 2002). The onset can be acute or start gradually. In most cases, there is a nonproductive cough, fever, chills, and headache. Diarrhea and a sore throat may be present. Respiratory symptoms may be absent, but occur in approximately one fifth of cases. Hepatitis, reactive arthritis, and erythema nodosum are less common manifestations. Abdominal symptoms may predominate. There may be splenomegaly. Auscultation may reveal vague rales, which is in contrast to the spread consolidations often seen at chest X-ray. Leukopenia, or at the most a slight increase in the number of white blood cells, are generally present (a hallmark of most human chlamydial infections). Rarely, meningitis, encephalitis, and myocarditis do occur. The infection may be fatal due to cardiovascular or respiratory insufficiency, which occurred in up to one third to one fifth of

Table 3 *Manifestations and consequences of infections by* Chlamydia psittaci *in humans*

Myocarditis
Reactive arthritis
Meningitis
Encephalitis

psittacosis cases before the antibiotic era and development of modern intensive care. At present, fatal cases are rare. Autopsy may reveal lung alveoli filled with exudate and extensive signs of pneumonitis.

PLACENTITIS AND ABORTION

Women handling infected sheep may contract infections with the 'ewe abortion agent' resulting in abortion, stillbirth, and premature birth. Humans can contract the infection by lambing sheep or taking care of newborn lambs. Pregnant women may become severely ill (Johnson et al. 1985). Signs of placentitis are found in cases where macroscopic inspection reveals microinfarction areas (Andrews et al. 1981). The histological picture is characterized by signs of infection of the trophoblasts. Caprine *C. psittaci* strains, i.e. '*Chlamydophila abortus*,' serovar 1, can cause placentitis and abortion in women. Infected goats may also abort (Pospischil et al. 2002).

CONJUNCTIVITIS

Cats may infect humans with the chlamydia feline conjunctivitis agent *Chlamydia (Chlamydophila) felis* (Ostler et al. 1969). Intrafamily spread of this eye infection occurs.

Infections in animals

A variety of clinical manifestations can be documented in animal infections by *C. psittaci*, e.g. ocular and central nervous infections, pneumonia, pericarditis, arthritis as well as intestinal (bowel) trachoma, and genital tract infections. Cats may get gastrointestinal infections causing diarrhea (Guillard et al. 1984). Infertility due to *C. psittaci* infection threatens the existence of the koalas in Australia.

CHLAMYDIA PNEUMONIAE

Epidemiology

Antibodies to *C. pneumoniae* is a common finding in population-based surveys. Seroprevalence figures from such studies from USA, Middle America, Spain, Japan, Taiwan, and New Zealand vary betwen 54–59, 62, 63, 48, 75, and 47%, respectively (Saikku et al. 1988). It is estimated that each individual as a mean will contract at least two to three infections by *C. pneumoniae* during their lifetime. It is notable, however, that there are very few isolates of the organism in relation to the claim that *C. pneumoniae* will infect the vast majority of individuals. Men more often have serological evidence of having acquired infections with *C. pneumoniae* than women. This also accounts for smokers. Great variations in the prevalence of *C. pneumoniae* serum antibodies have, however, been reported by time and geographic origin, in both children and adults. The group most commonly affected by *C. pneumoniae* is children 5–15 years of age.

The first evidence of the existence of respiratory tract infections with *C. pneumoniae* was based on an epidemic of such infections in Finnish military barracks in 1976 (Kleemola et al. 1988). In conscripts who had just arrived at the camp, 25 percent had such serum MIF antibodies in contrast to 47 percent of those who had been in the garrison during the epidemic. In another Finnish camp, this latter percentage was 51.

The difficulty of distinguishing a past infection from a current infection by *C. pneumoniae*, and crossreactions with other chlamydial species in serological tests has led some questions to the value of many early seroepidemiological studies. Thus, interpretation of early seroepidemiological studies of pneumonia cases must be made with caution if based on CF tests. This is due to the fact that the test does not differentiate between infections by *C. psittaci* (i.e. ornithosis cases) and infections by *C. pneumoniae*.

Children in developing countries seem to be more commonly affected by pneumonia by *C. pneumoniae* than those in industrialized communities.

Clinical conditions

Proposed and documented manifestations of infections by *C. pneumoniae*, are shown in Table 4.

UPPER RESPIRATORY TRACT INFECTION, INCLUDING CHRONIC BRONCHITIS

Most upper respiratory infections by *C. pneumoniae* seem to be rather mild, particularly in children. Asymptomatic infections do occur (Grayston et al. 1986; Schmidt et al. 2002). The infection is often self-limiting, but persistent infections do occur although they are uncommon in children. Endemic-like situations have been registered from time to time. A correlation between chronic carriership of *C. pneumoniae* and excerbation of chronic bronchitis has been demonstrated, as evidenced from analyses of sputum samples tested by nested touchdown PCR. Prolonged antibiotic courses have been recommended for effective clearance

Table 4 *Manifestations – documented and proposed – and sequelae of infections by* Chlamydia pneumoniae

Carotid artery stenosis
Aortic valve stenosis

of *C. pneumoniae* in cases with chronic bronchitis (Blasi et al. 2002).

PNEUMONIA

Infection with *C. pneumoniae* is regarded as one of the three most common etiological agents of community-acquired pneumonia (Monno et al. 2002). Lung infections with *C. pneumoniae* in children share a number of characteristics with that of *Mycoplasma pneumoniae* pneumonia (Nelson 2002). Double infections with the latter organism and *Streptococcus pneumoniae* is also common, which adds to the difficulty of managing such infections based only on case history, symptoms, and signs. Also, chest X-ray and laboratory tests involve differential diagnostic problems. Cough, fever, and fatigue are present in the majority of cases followed by rhinitis, pharyngitis, headache, and myalgia in almost half of all cases developing pneumonia (Table 5), while one or more symptoms of nausea, vomitus, dyspnea are found in approximately one fifth of the patients. Abdominal and chest pain, otitis media, sinusitis, diarrhea, bronchitis, erythema nodosum, exanthema, myocarditis, and pericarditis may be found, but infrequently.

To establish the diagnosis of *C. pneumoniae* pneumonia, serum samples should be collected for serological tests and sputum for antigen detection assays.

CHRONIC OBSTRUCTIVE LUNG DISEASE (COL, COPD, COAD) AND ASTHMA

Chronic infections by *C. pneumoniae* is believed to be involved in the development of COL (COPD, COAD) or chronic acute lung disease (Clementsen et al. 2002; Smieja et al. 2002). Progress of COL is linked to smoking, which is a behavioral factor not yet considered strong enough in studies searching a link between COL and *C. pneumoniae*. Almost half of all smokers will experience COL after 50 years of age. Neonatal pneumonia caused by *C. trachomatis*, like other types of pneumonia affecting babies and infants (Beem and Saxon 1977), may play an etiological role in COL.

Some studies claim an etiological role of *C. pneumoniae* in asthma (Clementsen et al. 2002), while others have not found the seroprevalence of *C. pneumoniae* antibodies to differ between asthmatic patients and controls. Use of corticosteroids in asthmatic patients interferes with the T helper (Th)-1 response and enhances a Th-2 response, which decreases the ability to clear intracellular infections, as that with *C. pneumoniae*. Detection of serum IgA antibodies to *C. pneumoniae* may be used to diagnose chlamydial infection in asthmatic patients. In contrast to coronary disease (see below), detection of chlamydial hsp is not a useful marker of chlamydial infection in patients with less severe asthma.

Table 5 *Symptoms and signs of infections by* Chlamydia pneumoniae *(C = common, i.e. >40 percent, LC = less common 39–11 percent, U = uncommon <10 percent).*

Symptoms and signs of infection	
Cough (C)	Abdominal pain (LC)
Fever (C)	Chest pain (U)
Fatigue (C)	Diarrhea (U)
Myalgia (C)	Exanthema (U)
Nausea (LC)	Arthritis (U)

CORONARY HEART DISEASE AND CONDITIONS AFFECTING NONCORONARY ARTERIES

Associations between *C. pneumoniae* and heart disease have been proposed, i.e. between early impaired coronary flow in heart infarction (coronary artery stenosis) and aortic stenosis. However, other studies deny any such correlation (Janatuinen et al. 2002). Many of the assumed correlations between *C. pneumoniae* and coronary heart disease have also been claimed for *Helicobacter pylori* (Bloemenkamp et al. 2002). hsp60 IgA antibody level is associated with coronary disease, especially in cases with documented *C. pneumoniae* infection and inflammation.

Carotid artery stenosis has been associated with *C. pneumoniae* in some, but not in other, seroepidemiological studies. An association between intimal calcification of femoral arteries in nondiabetic patients and serum antibodies to the organism has been demonstrated.

ARTERIOSCLEROTIC PLAQUE FORMATION

The first observation of a possible association between myocardial infarction and infection by *C. pneumoniae* was based on a serological study of Finnish men publised by Saikku and coworkers in 1988 (Saikku et al. 1988). *C. pneumoniae* infection has been associated with arteriosclerotic plaque formation, e.g. in coronary arteries (Kuo et al. 1993). Others have not found any impaired coronary blood flow in persons with *C. pneumoniae* antibodies (Janatuinen et al. 2002). *C. pneumoniae* antigen has been demonstrated in aortic valves in patients undergoing aortic valve replacement, but others have failed to make such a detection (Rose 2002; Vainio et al. 2002).

A large number of scientific groups have studied the possibility of a correlation between infections by *C. pneumoniae* and arteriosclerosis. However, the results have been contradictory both in seroepidemiological studies and in attempts to demonstrate the agent in arteriosclerotic plaques. The outcome of interlaboratory investigations of the same clinical material has given completely contradictory results, i.e. some laboratories have found evidence of an overall occurrence of *C. pneumoniae* infections in the samples tested, while others completely failed to do so. *C. pneumoniae* seropositivity has been correlated to thrombosis-related microembolization, but not to plaque-related embolization.

TNF-α is involved in the pathogenesis of artherosclerosis, but no link between this factor and *C. pneumoniae* has been demonstrated either to cardiovascular disease or dementia. A role of chlamydial hsp60 as a mediator of inflammatory response during infection by *C. pneumoniae* has been proposed (Costa et al. 2002).

Similar correlations as for *C. pneumoniae* and cardiovascular and other vascular diseases have been made with *Helicobacter pylori* (Fong et al. 2002) and recently also for cytomegalovirus (CMV) (Bloemenkamp et al. 2002) and herpes virus. This has changed the point of argument that rather the total 'infectious load' – perhaps from childhood – is more important for the development of arteriosclerosis than any single agent.

Experimental infection by *C. pneumoniae* in mice (Liuba et al. 2002) and rabbits accelerates arteriosclerotic plaque formation, which has been used as an argument for an etiological link. However, the study designs used did not clearly show if the inoculation dose caused an infection or rather a vaccination. If the latter is true, the possibility of a terrifying side effect of vaccination against *C. pneumoniae* could be assumed.

INFLAMMATORY BOWEL DISEASE

Some studies claim a role of *C. pneumoniae* in inflammatory bowel diseases, but the results are highly conflicting. Studies have confirmed the common presence of *C. pneumoniae* in colonoscopic biopsies in cases of Crohn's disease and ulcerative colitis. However, no significant difference with controls without evidence of any inflammatory bowel disease could be demonstrated (Chen et al. 2002). It is considered that many microbes, including bacteria and viruses, passing the intestine may co-act with chlamydia to produce an inflammatory response promoting development of pathological processes in vessels.

CNS DISEASES AND PERIPHERAL NERVE SYSTEM ENGAGEMENT

As for several other syndromes, a possible correlation between multiple sclerosis (MS) and late onset Alzheimer's disease on one hand, and *C. pneumoniae* on the other, have given conflicting results. A significant difference in the prevalence of antibodies to *C. pneumoniae* in patients with acute ischemic stroke and controls has been detected (Ngeh et al. 2003). However, other recent studies have not come out in the positive for an etiological role of *C. pneumoniae* in any of these CNS conditions.

DIAGNOSIS

Microscopy

In earlier days, Giemsa was used to strain EBs, which are eosinophilic in contrast to the basophilic RBs. Also, dark-field microscopy can be used to detect chlamydia organisms where EBs appear as yellow bodies due to their natural autofluorescence. Microscopy, using monoclonal antibodies to *C. trachomatis* (Tam et al. 1982), is a rapid means of detecting chlamydia EBs in eye secretion in conjunctivitis cases. The sensitivity of immunoflourescence (IF) tests of genital secretion is problematic in more longstanding infections where the number of EBs has often become low. The use of IF tests for urine specimens is also a problem, as there are many artifacts in the samples that can mimic EBs. It is rare to detect chlamydial inclusions in clinical samples. The advantage of IF tests is that the answer may be obtained rapidly. Unfortunately, IF tests have been used by inexperienced staff in many countries, which has resulted in a large number of false-positive diagnoses.

Culture

Commercial interests once colored the debate about which is the best method for diagnosing genital chlamydial infections, in which the value of culture was underscored. The most widely applied culture method in current use is application of cycloheximide-treated McCoy cells (Ripa and Mårdh 1977). Cycloheximide inhibits the protein metabolism of the host cell, thereby favoring growth and multiplication of chlamydia organisms, as being energy-parasites stealing ATP from the host cell. Chlamydial inclusions in cell cultures can be easily detected by iodine staining of the cell carpet, where inclusions stain brown in contrast to the yellow color of the host cells. Inclusions can also be detected by staining with monoclonal antibodies by which they appear intensively apple green (Stamm et al. 1983). Counterstain with rhodamine B gives the cells a red color, which makes the detection of chlamydia-positive cases easier and the picture is attractive to the eye (Figure 10). To establish the diagnosis, at least ten EBs have been recommended to be used as the cut-off

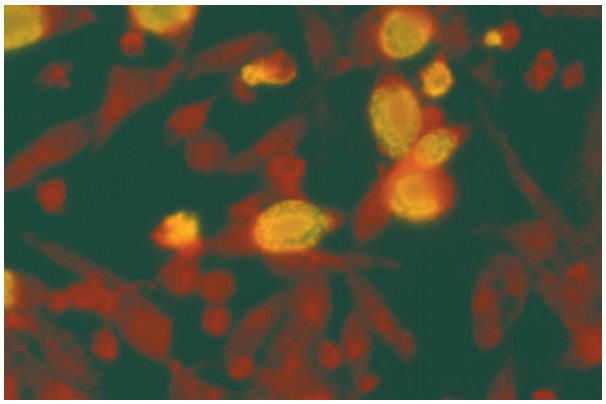

Figure 10 *Intraacytoplasmatic inclusions of* Chlamydia trachomatis *in cycloheximide-treated McCoy cells cultures stained with labeled monoclonal antibodies. Cell carpet counterstained with rhodamin B*

level. A lower cut-off can be accepted, but must be related to the experience of the microscopist. However, a high cut-off will mean that chlamydia-infected individuals may be falsely classified as negative.

The use of both urethral and cervical cultures has been recommended for detection of genital chlamydial infections, increasing the positive rate by approximately 5 percent. However, if taking consecutive samples from the cervix at the same time, the sensitivity of culture studies will also increase. The third consecutive sample collected with cotton-tipped swabs from the cervix yielded the highest positive rate. Use of urine for culture is inadequate, as the positive rate is only 30 percent compared to cervical samples from the same individuals. The current sampling recommendation is to use the first collected cervical swab for gonococcal culture (or discard it) and thereafter collect a sample for chlamydia culture (Mårdh et al. 1981b). The type of sampling swab used is essential, as both cotton and wood sticks can be highly toxic to chlamydia organisms, due to calcium alginate and resins, respectively (Mårdh and Zeeberg 1981).

With the exception of serovars L 1–3, EBs produced in primary cultures of clinical samples do not enter uninfected cells after being released. In the case of LGV, more or less the entire cell carpet may contain inclusions. This characteristic can be used as a diagnostic marker for LGV.

C. psittaci can be grown by the same principles as for *C. trachomatis*, but the high risk for laboratory infections has made serology preferable. *C. pneumoniae* is difficult to get to multiply in tissue cell culture, which may explain the very limited number of strains of this species that have been isolated. Using the same methods as for isolation of *C. trachomatis*, i.e. cycloheximide-treated McCoy cells, the inclusion count of *C. pneumoniae* in primary cultures is extremely low. HeLa cells treated by DEAE-dextran have been proposed to be a better choice, like human lung (HL) cells. The few inclusions that show up are generally small in size (Figure 11). *C. pneumoniae* is also difficult to propagate in tissue cell cultures.

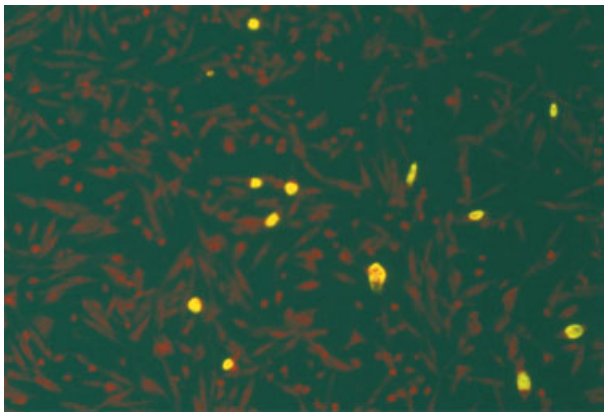

Figure 11 *Intraacytoplasmatic inclusions of* Chlamydia pneumoniae *in McCoy cells stained with immunofluorescent antibodies. Cell carpet counter-stained with rhodamin B.*

Cultures may serve the purpose of allowing rapid test of microbial cure after antibiotic therapy, that is, during the second to third weeks after finishing treatment. DNA tests may then still be positive due to the presence of dead, but not yet shed EBs. The use of cultures as a diagnostic method also offers the possibility of performing antibiotic susceptibility tests of isolated strains and detecting nonplasmid-containing strains.

Geno- and serotyping of clinical isolates

Serotyping of isolates of *C. trachomatis* has so far only been performed in an epidemiological context (Persson 2002). Serovars A, B, Ba, and C of *C. trachomatis* have generally been connected with trachoma, although also D (generally connected with genital infections and inclusion conjunctivitis) may sometimes cause trachoma. Serovar B may also infect genital organs. Serovar E is predominant in nontrachoma areas, e.g. in North America, Europe, and South Pacific. It often outnumbers the prevalence of all other serovars together. Double infections with more than one serovar do occur, but are not common. It seems fair to conclude that there is no strong evidence for a virulent advantage of any of the serovars.

Genotyping by sequencing the chlamydia MOMP gene has revealed subtypes within serovars of *C. trachomatis* (Frost et al. 1991; Pedersen et al. 2000).

ELISA

ELISA tests were widely used to diagnose genital chlamydial infections. Such tests are still in use in economically less developed countries, mainly because of the price being lower than for DNA-based tests. Because of the low specificity, it has been recommended to use confirmatory tests in case of a positive ELISA test, such as in Chlamydiazyme® tests. In ELISA tests, immobilized LPS antibodies bind the LPS antigen. A secondary antibody linked to an enzyme causes a color change that can be registered optically. 'Gray zone' results is a dilemma with these diagnostic tests. The results falling within this zone must be rechecked with confirmatory tests (Mårdh et al. 1990). This delays the return of answers to the clinician. If the cut-off is increased, the sensitivity will, of course, decrease. Other problems are crossreactions with *Staphylococcus aureus* and gram-negative bacterial species, such as *Escherichia coli*. This problem is accentuated when rectal, urine, and pharyngeal samples are to be tested (not recommended).

Nucleic acid and ribosomal tests

At present, nucleic acid amplified tests (NAAT), such as Cobas Amplicor, Roche (PCR) (Livengood and Wrem 2001), LCR (i.e. LcX, Abbott (Lee et al. 1995) and

real-time PCR tests, have been recommended for the diagnosis of genital chlamydial infections. The last method is more sensitive than nested touchdown PCR techniques. PCR and LCR tests for *C. trachomatis* are based on DNA sequences in the cryptic plasmid found in all such strains, but with a few documented exceptions (Peterson et al. 1990). Real-time PCR has been employed to detect *C. pneumoniae* antigen (Bennedsen et al. 2002).

There were initial problems with Taq-polymerase inhibitors and DNA contamination during sample handling, particularly after amplification. Adding inhibitors of potential inhibitors to the kits has solved these problems to a large extent, together with the development of closed sample systems, and chemical sterilization of amplified products. In-house nucleic acid test results from research laboratories that have not taken such precautions must be analyzed with caution. In low prevalence populations, there are problems with the positive predictive value in DNA tests, creating management problems. Clinicians being in charge of patients who mainly belong to a low prevalence group for genital chlamydial infections are recommended retesting of all patients with a positive test result (preferably with another diagnostic test) to avoid false diagnoses.

Chlamydia 16S-rRNA genes have been utilized in recently introduced commercial tests. Transcription-mediated amplification (TMA) tests make use of rRNA as target. These tests have a clinical value similar to that of the DNA-based tests. In the past, Gene-Probe® was the most commonly applied ribosomal RNA test used.

The introduction of DNA and RNA tests meant an increased sensitivity and specificity of chlamydial diagnostic services. Paradoxically, the introduction of automated systems handling NAAT analyses increased the specificity of chlamydial tests in units staffed with inexperienced technicians formerly involved in subjective tests, such as reading of IF tests and cultures.

Some commercial NAAT kits, e.g. for PCR and LCR tests, are offered as a package of tests for both *C. trachomatis* and *Neisseria gonorrhoeae* (Livengood and Wrem 2001).

In LCR tests (Stary et al. 1997), swabs from the vaginal introitus yield a somewhat higher positivity rate than samples collected from the cervix of the same women. Self-swabbing of the introitus by women themselves resulted in an even somewhat higher percentage of positive cases then when the sampling of the same women was performed by medical personnel.

Doctor' s office tests

Doctor' s office tests for the diagnosis of genital chlamydial infections, such as Clearview® and Surecell®, have a low accuracy compared to NAAT tests. One advantage of the former tests is, however, that the result can be obtained when the patient is still at the clinic.

Serology

Tests for antichlamydial antibodies have made use of both chlamydial LPS and MOMP as antigen. Chlamydial LPS is shared by all chlamydial species. As LPS of *C. trachomatis* crossreacts with *C. pneumoniae* and *C. psittaci* and was easy to produce, it was in the past made use of in complement-fixation (CF) tests used for diagnosing LGV and ornithosis/psittacosis (Mårdh et al. 1989). Recombinant MOMP and recombinant OMP-2 have been used to detect antichlamydial antibodies. A species-specific peptide has been identified, which avoids crossreactivity problems in serological assays of chlamydial infections by the various species (Närvänen et al. 1997).

In MIF tests (Wang and Grayston 1982), chlamydia antigen can be applied on a glass slide and a panel of known serovar-specific antibodies can be used to determine the identity of the antigen. Antigens of known serovars of *C. trachomatis* can also be used to test for the presence of serovar-specific antibodies. The use of LPS-free preparations of chlamydia antigen in MIF tests have demonstrated crossreacting antibodies to other chlamydia species being common, particularly during early onset of the immune response (Domeika et al. 1997). Thus, the antibody response becomes more species-specific after the onset of antibody production. A Washington Research Foundation, Labsystems, and MRL Diagnostics kits for MIF tests can be used to detect IgM, IgG, and IgA antibodies to *C. pneumoniae*. The value of real-time quantitative PCR for detection of *C. pneumoniae* has been evaluated (Mygind et al. 2002).

Serology has so far not been a useful means for diagnosing ongoing genital chlamydial infections. The fact that both IgA and IgG antibodies to *C. trachomatis* occur in a high percentage of women with no evidence of a current genital chlamydial infection means that the positive predictive value is unacceptably low. PID patients may lack IgM antibodies to *C. trachomatis*, which might be due to cervicitis which has preceded the tubal infection by some time. Serological tests have been of value in seroepidemiological surveys. Serological tests are, however, of clinical significance in the diagnosis of neonatal pneumonia in which a positive antichlamydial IgM antibody test, is a pathognomonic sign (Persson 2002). The presence of IgA antichlamydial antibodies has been believed to predict a persistent chlamydial infection, as IgA antibodies in general disappear quicker than IgG antibodies. A test for IgG antibodies to *C. trachomatis* has also been argued to be a screening test for tubal occlusion due to a previous chlamydia infection and to support the

diagnosis of ectopic pregnancy. These three latter proposals have, however, been opposed as being clinically useful. Presence of hsp60 antibodies to *C. trachomatis* seems to be a better predictor of tubal factor infertility and ectopic pregnancy than demonstration of MIF antibodies to the agent.

In human *C. psittaci* infections, e.g. in ornithosis/psittacosis, IgM antibodies are often lacking or occur in only low titers, while seroconversion of IgG antibodies can usually be demonstrated. However, a significant IgG antibody change may take up to 3 weeks. Also IgA titer rises can be seen. CF tests using LPS-containing antigen will involve the risk of crossreactivity with other chlamydial species. MIF tests have also been used for antibody detection.

ANTIBIOTIC SUSCEPTIBILITY

Until recently, antibiotic susceptibility tests have played an unimportant role in the management of infections by *C. trachomatis* (Persson 2002) in the belief that all strains are susceptible, at least to erythromycin, azithromycin, and tetracycline drugs, such as doxycycline. However, there are now reports of strains with high minimum inhibitory concentration (MIC) values to erythromycin (i.e. >1 μg/ml) and tetracycline (i.e. >4 μg/ml) (Lefevre and Lepaargneur 1998; Somani et al. 2000). Single strains with a reduced susceptibility to azithromycin and to quinolones, e.g. to ofloxacin, have been linked to therapeutic failure. However, there have been difficulties obtaining interlaboratory consistent susceptibility determinations, which have been an obstacle in the interpretation of such tests and of their clinical significance. Chlamydia organisms lack muramic acid, but the presence of two penicillin-binding proteins may explain their susceptibility to betalactam antibiotics, provided enough high doses are given for at least 2 weeks.

Chlamydia-positive cases at retests have usually been regarded as cases of reinfection or due to compliance problems rather than to antibiotic resistance. However, there seems to be a mandatory task to start to routinely survey the existence of resistant strains of *C. trachomatis* in different geographic locations and to develop surveillance systems for registration of nonsusceptible strains.

Under antibiotic pressure, *C. trachomatis* may, in in vitro tests, develop decreased susceptibility to the drug under test. Such strains usually lose their antibiotic resistance when propagated in absence of the antibiotic. Such heterotypic resistance has, however, not been connected to therapeutic failure (Schmid et al. 2001). Subinhibitory concentrations of betalactam antibiotics may induce RBs which are insensitive to this group of antibiotics. This might explain relapses after use of betalactam antibiotics. RBs are naturally also insensitive to some other antibiotics, which may be another reason for relapses after antibiotic therapy.

ANTICHLAMYDIAL ACTIVITY OF BODY FLUID

Body fluids possess antichlamydial activity, e.g. amniotic fluid (Elbagir et al. 1989a), cervical secretion (Mahmoud et al. 1994b) (with varying effect during the menstrual cycle), saliva (Genc et al. 1994), and seminal fluid (Mårdh et al. 1980a). The seminal fluid activity may explain why chlamydial infections of the male accessory genital glands are rare, compared to PID. The antichlamydial activity of tear fluid (Elbagir et al. 1989b) may explain why transient colonization is more common than conjunctivitis in infants born to mothers with genital chlamydial infection (Mårdh et al. 1980a). The antichlamydial activity of human milk (Elbagir et al. 1990) may also have a protective effect against the development of neonatal chlamydial infections.

THERAPY

Chlamydia trachomatis

Protein inhibitors, e.g. tetracyclines, erythromycin, and azithromycin, are all first-line alternatives in the therapy of chlamydial infections, apart from tetracycline in pregnancy (Brihmer et al. 1995; Carlin and Baron 1996; Magid et al. 1996; Genc 2002; Guaschino and Ricci 2002). Other macrolides, such as roxithromycin and josamycin seem to have a somewhat lower activity than erythromycin, which can be compensated with higher doses and/or prolonged courses (Stenberg and Mårdh 1993).

Azithromycin is a derivative of erythromycin, classified as an azilide antibiotic. It has the advantage that it is rapidly and efficiently taken up by eukaryotic cells, where it can reach chlamydia organisms. Another advantage is that azithromycin can be given as a single dose regimen, i.e. with 1 g. The drug also persists in the body for a period similar to a standard multidose regimen with tetracyline. Azithromycin therapy with this dose can be instituted at the clinic before a chlamydia-positive patient leaves. This means that one can avoid any compliance problem, which often arises with the multidrug intake required when using tetracyclines. Azithromycin can be used in pregnancy (Genc 2002). Doxycycline should be given with 200 mg per day both to men and women; in men for at least 7 days and in women preferably for 10–14 days. Different dose regimens for uncomplicated and complicated genital chlamydial infections in women is artificial, as almost half of all women infected by *C. trachomatis* have a PID (at least endometritis). It is not possible to identify women with PID without performing endometrial aspiration and histological investigation of the aspirate. Such an invasive procedure is unrealistic to perform on a routine basis

and involves risk to facilitate ascendance of chlamydia organisms to the upper genital tract.

Amoxicillin is listed as a second-line therapeutic alternative with a dose regimen of 500 mg three times a day for 7 days. For pregnant women, the best alternative is 1 g of azithromycin or amoxicillin 500 mg for 10 days (Genc 2002). Pregnant women tolerate these drugs better than erythromycin.

Quinolones are chlamydicidal in action (Guaschino and Ricci 2002). However, quinolones are regarded as second-line alternatives in chlamydial infections because of their comparatively low efficacy. Quinolones are contraindicated in pregnancy. Clindamycin, commonly used to treat bacterial vaginosis and to treat upper genital tract infections, has a too low activity against chlamydia organisms to be a drug of choice. This also accounts for chloramphenicol, sulfonamides, and aminoglycosides.

Co-infection with *N. gonorrhoeae* and *C. trachomatis* should be considered in any case in which such infections might be involved (Genc and Mårdh 1997). Some decades ago, roughly one quarter of all cases of either gonorrhea or genital chlamydial infection in Swedish STD and gynecological clinics, had such a double infection.

Treatment guidelines have been given for various situations in genital and allied infections by *C. trachomatis*, e.g. those produced by the Center for Disease Control and Prevention in the USA (CDC Guidelines 2002) and those of the Association of Genitourinary Medicine in UK (National guidelines for 1999).

Local therapy with tetracycline ointment has long been used to treat trachoma (Darougar and Jones 1983), but local therapy with azithromycin is likely to be more effective. General azithromycin therapy is even more effective in this disease (Holm et al. 2001).

Chlamydia psittaci and *Chlamydia pneumoniae*

Human infections by *C. psittaci* should be treated with the same drugs as in infections with *C. trachomatis*, i.e. with one of tetracycline, erythromycin, and azithromycin.

Resolution of pulmonary infection by *C. psittaci* usually starts after 1 week, although it can be longer. Psittacosis resolves in a fortnight to 1 month. Relapses do occur. Reinfection may occur from untreated caged birds. Prophylactic therapy in flocks of birds and non-avian herds infected by *C. psittaci* varies in efficiency.

Treatment of pneumonia with *C. pneumoniae* should be the same as in psittacosis.

Prophylactic antibiotic therapy of persons at risk for coronary heart disease did not result in a decreased rate of heart infarction, and neither did azithromycin prevent coronary heart infarction (Gupta et al. 1997). Treatment, for example with amoxicillin, metronidazole, azithromycin, or omeprazole reduced adverse cardiac events, but the effect was independent of *C. pneumoniae* and *Helicobacter pylori* seropositivity (Stone et al. 2002). Aspirin, and its derivate salicylic acid, had a positive effect on cardiovascular adverse events. The cardioprotective effect of salicylic acid, regarding infections by *C. pneumoniae* and ischemic heart disease, is believed to be mediated by induction of nuclear factor (NF)-kappa B production. This inhibits growth of *C. pneumoniae* and production of interleukines, such as IL-6 and IL-8 (Tiran et al. 2002). Once a month roxithromycin therapy for at least 2 years reduced the progress of peripheral arterial occlusion in a randomized, double-blind, placebo-controlled trial (Wiesli et al. 2002). Likewise, treatment with 150 mg roxithromycin twice daily for 1 month, reduced progress of early carotid artery arteriosclerosis in stroke patients followed-up for 2 years. The effect was best in *C. pneumoniae* seropositive cases (Sander et al. 2002). Reduction or cessation of smoking and regulation of diabetes are among possible confounding factors in heart infarction, the influence of which must be considered in evaluation of prophylactic antibiotic therapy in artery vessel diseases, like the weakness in the diagnostic tools for diagnosing *C. pneumoniae* infections (Broman and Hammerschlag 2002).

CHLAMYDIA SCREENING AND RESCREENING

As the majority of infections by *C. trachomatis* both in men and women are more or less asymptomatic, infected persons have generally no motivation to consult. Therefore, it is essential to perform screening to detect carriers (Genc et al. 1993; Genc and Mårdh 1996; Svensson et al. 1994). This is important as hindering spread of the organism to uninfected individuals will avoid adverse immunological reactions, which may continue even after microbiological cure in people who have contracted the infection.

Screening should be accompanied by partner notification. This is generally highly rewarding, as usually more than half of sexual consorts are chlamydia-positive. There is an obvious need for rescreening persons positive for *C. trachomatis*, as either relapse or reinfection is common in genital chlamydial infections (Mårdh and Persson 2002).

Voided urine or samples from the vaginal introitus collected by self-sampling with mailed or otherwise distributed sampling kits, allow mass screening of populations for *C. trachomatis* (Östergaard et al. 1996).

The pay-off of performing intensive screening programs has been calculated from computer modeling (Genc and Mårdh 1996). In Sweden, just over half a million chlamydia tests were performed for a number of years during the 1980s (in a population of approximately 8.5 million) (Mårdh 2002b). Apart from reduction of the

prevalence of genital chlamydial infections, the number of PID and extrauterine pregnancies decreased sharply after the screening activities (Weström 1998). Screening of selected groups has also proved effective to prevent complications from infections by *C. trachomatis*, for example in women about to undergo abortion (Osser and Persson 1984).

INTRODUCTION

Rickettsiae were historically defined as small gram-negative intracellular bacteria. This definition is very weak and has required that many organisms previously named *Rickettsia* needed to be reclassified. This includes *Coxiella burnetii* (first named *Rickettsia diasporica*), *Neorickettsia sennetsu* (first named *Rickettsia sennetsu* and then *Ehrlichia sennetsu*), *Ehrlichia canis* (first named *Rickettsia canis*), and *Bartonella quintana* (first named *Rickettsia quintana*, and lately *Rochalimaea quintana*), among others. The past 20 years have seen significant changes in the field. Three major changes include the reclassification of the Rickettsiales, the description of many new emerging rickettsial diseases, and the beginning of the genomic era for intracellular bacteria.

The universal gene encoding for 16S rRNA has been widely used for the classification of bacteria. It is particularly useful for intracellular bacteria such as rickettsiae because so few phenotypic criteria are available. Many genera were reclassified following 16S rRNA sequencing. The *Orienta* genus was created from an independent branch of the *Rickettsia* genus phylum (Tamura et al. 1995). The 'ehrlichia' group was recently reclassified (Dumler et al. 2001) into four genera, including *Ehrlichia* and *Anaplasma*, which are associated with ticks, *Neorickettsia*, which is associated with helminths, and *Wolbachia*, which are associated with both arthropods and helminths (Figures 1 and 2). The genus *Cowdria* has been abandoned and many species have been reclassified into other genera. The *Bartonella* genus is a close neighbor in the alpha group of proteobacteria and now comprises the former *Rochalimeae* species, *Grahamella*, and *Wolbachia melophagi*. *Coxiella* and *Rickettsiella* are now in the gamma group of proteobacteria closely related to *Legionella* species and *Francisella tularensis*. *Wolbachia persica* is a species in the genus *Francisella*. The more distantly related *Eperythrozoon* and *Haemobartonella* genera, including erythocytic animal pathogens that were classified with *Anaplasma*, are in fact closely related to mycoplasmas and issue from the gram-positive lineage.

Until the use of cell cultures and molecular amplification with typing for *Rickettsia*, identification was based on culture in animals and embryonated eggs. The description of new *Rickettsia* species was very slow. Since 1980, many new *Rickettsia* and rickettsial diseases have been found and more rickettsioses and ehrlichioses have been reported (Table 1). The new genetic tools, as well as the use of cell culture assays, have allowed for the discovery of many new rickettsioses and ehrlichioses in the past 20 years (see Table 1) (Raoult and Roux 1997), including three ehrlichioses and ten rickettsioses that have since been described. Three major conditions determined the discovery of new rickettsioses. Some were discovered following clinical descriptions in

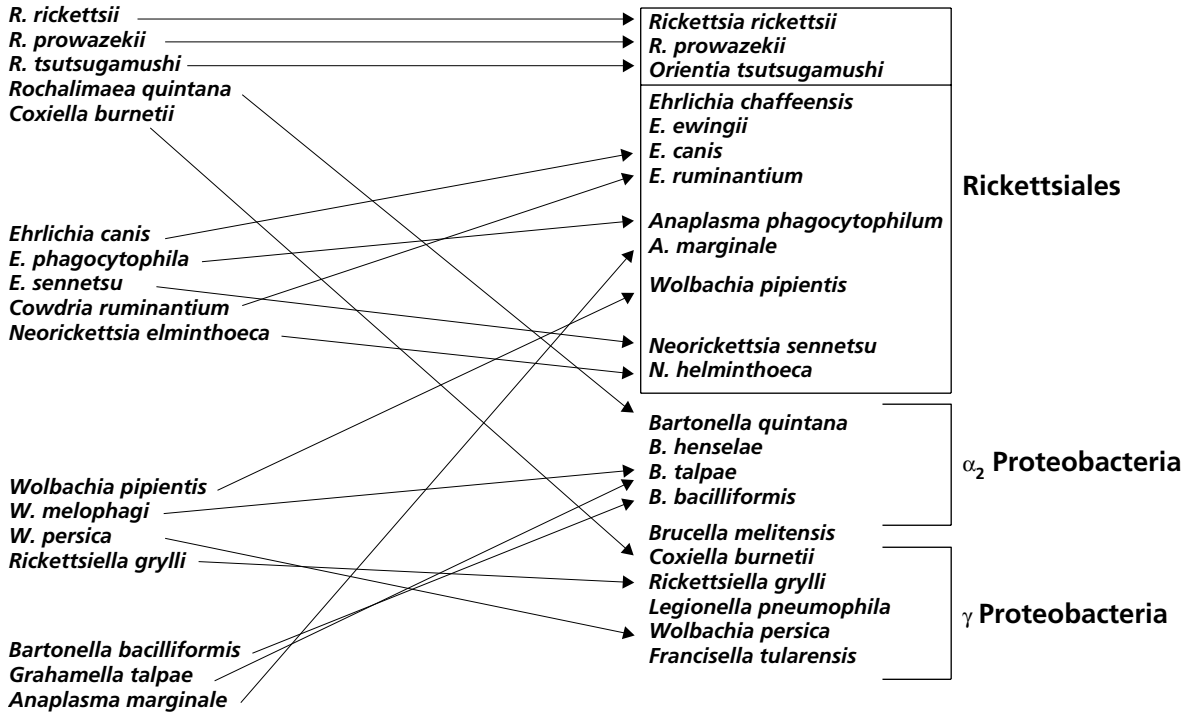

Figure 1 *Current classification of the Rickettsiales (right column) compared with the former classification (from 1984) (left column).*

countries where spotted fever was unknown (Japan and *R. japonica* (Mahara 1997), Flinders' Island and *R. honei* (Stenos et al. 1998), and Russia and Astrakhan fever (Tarasevich et al. 1991)). Some were recognized after bacterial identification based on culture and polymerase chain reaction (PCR) in places where the new pathogen was confused with another known rickettsial pathogen (*R. africae* (Raoult et al. 2001b), *R. mongolotimonae* (Fournier et al. 2000a), and *R. aeschlimanii* (Raoult et al. 2002b) with *R. conorii*, *R. felis* (Schriefer et al. 1994) with *R. typhi*). Finally, some were identified by the collaborations of physicians and microbiologists who faced atypical or unknown diseases (*R. slovaca* (Raoult et al. 2002a) and *R. helvetica* (Fournier et al. 2000b) (Raoult and Roux 1997)).

Many *Rickettsia* in their arthropod hosts were initially identified long before their implication as a human pathogen (Raoult and Roux 1997). The denomination 'nonpathogenic' rickettsia is therefore highly speculative and has later been proven untrue in many instances. For example, *Coxiella burnetii* and *Legionella pneumophila* were considered 'nonpathogenic.' Among rickettsiae, *R. felis* and *R. africae* were identified in their vectors long before being implicated as human pathogens.

Two species, *R. prowazekii* (Andersson et al. 1998) and *R. conorii* (Ogata et al. 2000, 2001), were among the first 50 sequenced bacterial genomes. They are considered paradigms of the intracellular bacteria with small genomes. Genomic studies have shown that *R. prowazekii* should be considered as a subset of *R. conorii* that has incompletely evolved in its current niche, as attested by the large proportion of noncoding DNA in the former species. This noncoding DNA consists mainly of remnants of genes found in *R. conorii*. Genome analysis showed that both rickettsiae have multiple copies of ATP-ADP translocase genes (a parasitic enzyme that allows the importation of adenosine triphosphate (ATP)), spot T (an alarmone that is secreted in other microorganisms with starvation), and proline/betain transporters. The analysis of *R. conorii* also exhibited two new strategies of bacterial evolution. Palindromic repeats that can integrate into coding genes were found (Ogata et al. 2000, 2002). The different steps of evolution from complete gene to a gene remnant through a 'splitting' phenomenon were also described (Ogata et al. 2001). Genome analysis of metabolic pathways that are lacking in Rickettsia may provide a rational basis for design of medium culture for the axenic growth of *Rickettsia* species, an ultimate goal for rickettsiologists.

HISTORY

Typhus is suspected to be the cause of many huge, historical outbreaks including the plague of Athens, as described by Thucidides in the fifth century BC. However, it is still controversial whether this event can truly be attributed to typhus. One theory proposes that typhus was imported from America after Columbus' return. This theory matches with the fact that the only nonhuman reservoir identified currently is in America in flying squirrels (Dasch et al. 1978). The first description of a disease compatible with typhus was made by

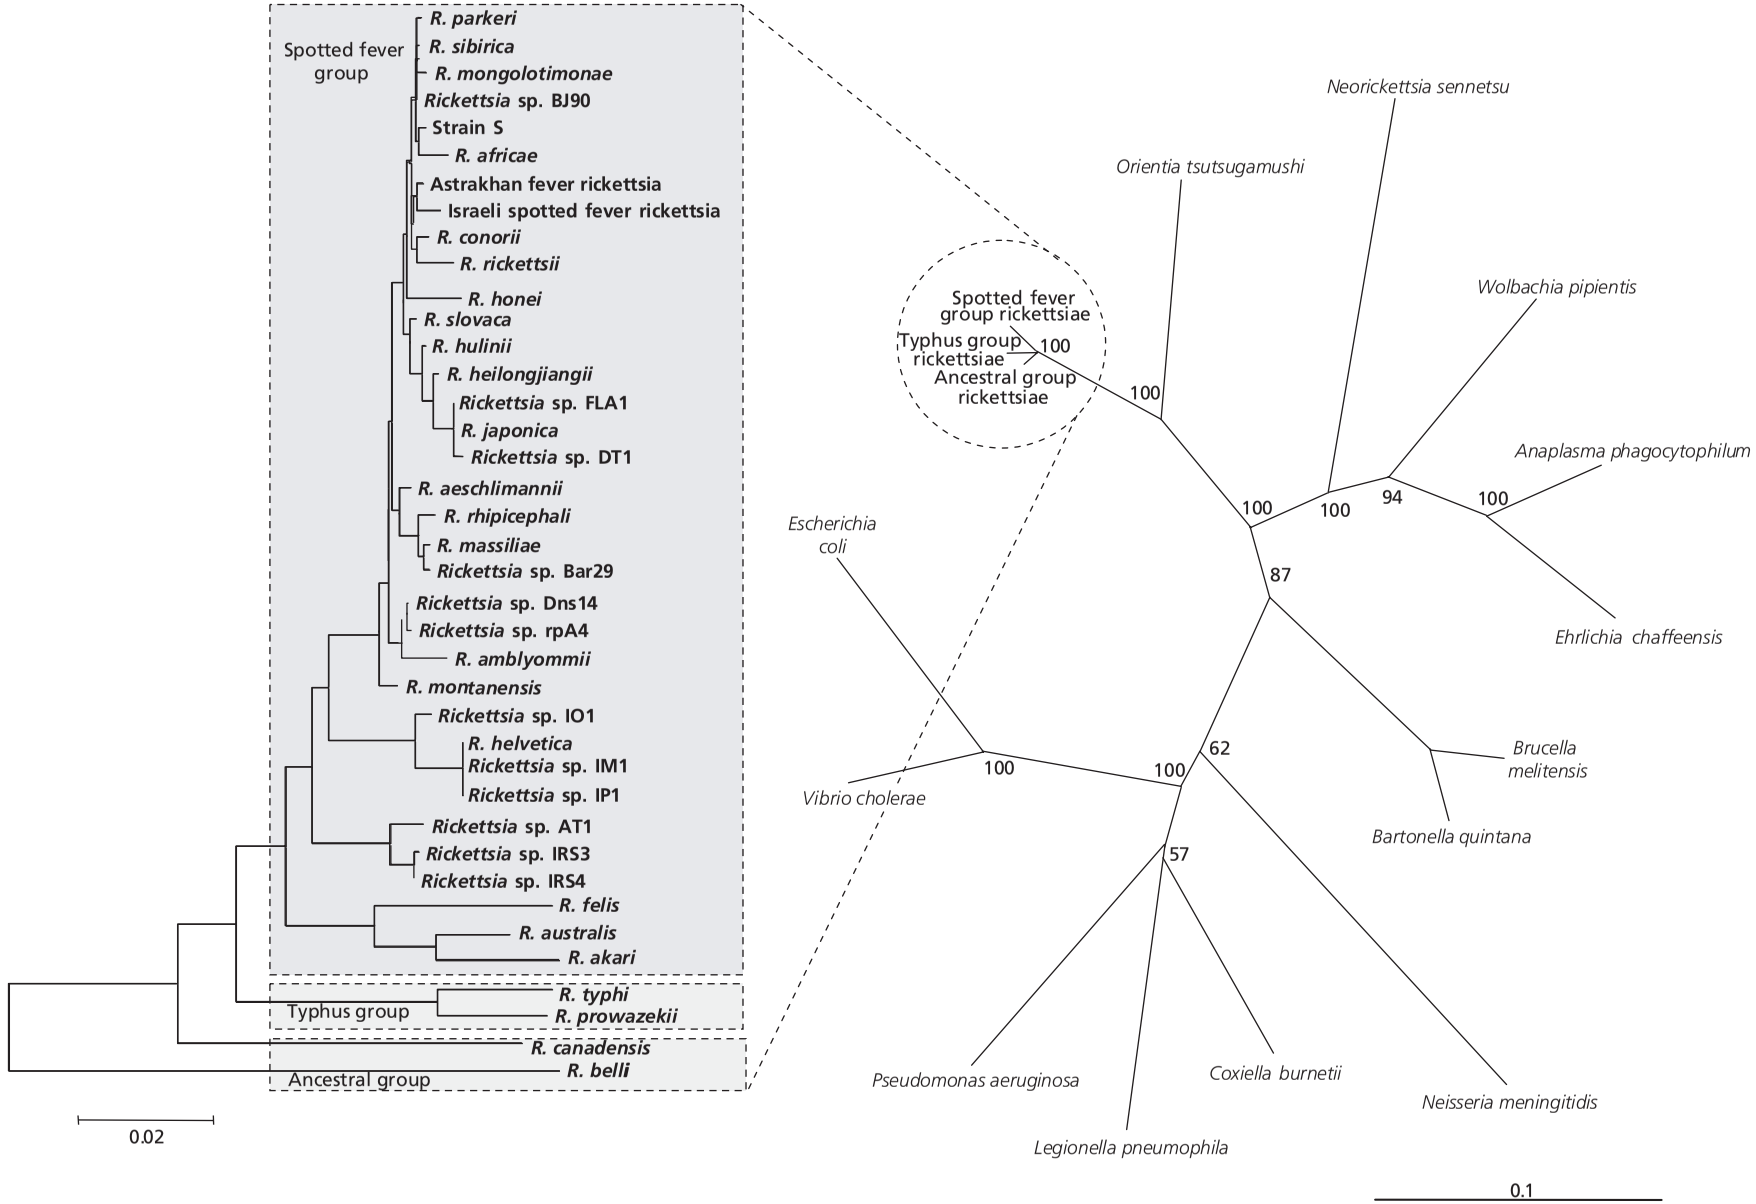

Figure 2 *Phylogenic tree including Rickettsiales and bacteria previously included in this group. The large tree (right) is obtained by the neighbor-joining method based on 16S r RNA; the left tree is based on citrate synthase and rOmpA.*

Fracastor. Typhus was included with typhoid in the group of diseases in which patients suffered fever and typhos (which in Greek means 'change in mental status'). Several authors, including Boissier de Sauvage in 1760 (Weiss, E. 1988), proposed a scheme to differentiate these two diseases (see Table 1). Typhus was first properly described by Von Hielderbrand in 1810 (Weiss, E. 1988) after the outbreak in Napoleon's army (Weiss, E. 1988; Weiss, K. 1988). Gerhard (Weiss, E. 1988) described the pathological differences in these two diseases in 1832. It is generally accepted that typhus and louse-transmitted diseases killed more than half of the 700 000 men of Napoleon's army during the Russian campaign in 1812 (Zinsser 1935). It also killed millions during the First World War and five million Russians during the Bolshevik revolution. During the Second World War, outbreaks were noted in concentration camps in North Africa and in Italy. The association of

MSF, Mediterranean spotted fever; RMSF, Rocky Mountain spotted fever.

fever, rash, and neurologic involvement became the hallmark of rickettsial diseases. Rocky Mountain spotted fever in 1899 and Mediterraneous spotted fever were described based on these basic clinical findings.

The etiologic agents of these diseases were not found easily. They do not grow in basic axenic media. *Proteus* species were isolated from the urine of patients with typhus and were erroneously considered to be the etiological agents. By chance, they cross-react with rickettsia and were used in the first serological assay (the Weil–Felix test). Culture of the rickettsial agents was difficult but was finally obtained in laboratory animals at the beginning of the twentieth century (see Table 1). Rickettsial diseases have been among the most deadly in history. It was also very dangerous to work on these diseases and two famous rickettsiologists, Ricketts and Von Prowazek, died of typhus. Da Rocha Lima named the causative agent of typhus in their honor: *Rickettsia prowazekii*.

Charles Nicolle identified the role of body lice in the transmission of typhus and its agent, and the role of ticks in transmission of the causative agent of Rocky Mountain spotted fever was definitively established by H. Ricketts (see Table 1). He was also the first to isolate *Rickettsia rickettsii*.

Rickettsiae were grown first in animals. Guinea pigs (for *Rickettsia* spp.) and mice (for *Orientia*) were used. The scrotal reaction of interperitoneally infected guinea pigs allowed differentiation between *R. typhi* (first named *R. mooseri*) and *R. prowazekii*. As animals shed living organisms, manipulation of rickettsia was very dangerous. Until the discovery of the role of chloramphenicol in the treatment of typhus during the Second World War by Woodward, it remained a dangerous field (Weiss, K. 1988).

MICROBIOLOGY

The rickettsiae are intracellular parasites. They are small gram-negative bacteria that live freely in the cytoplasm of their infected eukaryotic host cells. Rickettsiae induce phagocytosis and rapidly escape from the phagocytic vacuole to live in the cytoplasm. Escape from the phagosome may be due to activation of a phospholipase. Phospholipase A2 was believed to be involved (Walker et al. 2003); however, a phopholipase A2 gene is not present in the genomes of *R. prowazekii* or *R. conorii*. It may be that phospholipase D, which is secreted by *R. conorii*, is in fact the key enzyme for intracellular parasitis (Renesto et al. 2003). Spotted-fever-group rickettsiae can grow in both the cytoplasm and the nucleus of infected cells, and they can also escape from living cells. Typhus-group rickettsiae grow in the cytoplasm only and are released when the heavily infected host-cell membranes are destroyed. This difference is determined by the intracellular motility of SFG rickettsiae, which is in turn determined by polymerization of host actin (Teysseire and Raoult 1992; Teysseire et al. 1992). *R. typhi* have limited motility and actin polymerization does not occur in *R. prowazekii*-infected cells. By comparing the genomes of *R. prowazekii* and *R. conorii*, it was speculated that a gene encoding for a protein resembling ActA that is involved in *Listeria monocytogenes* may be responsible for the ability to polymerize actin (Ogata et al. 2001); this theory has been confirmed (Harlander et al. 2003; Gouin et al. 2004).

Rickettsiae are 0.3–0.5 μm in diameter and 1–2 μm in length. As they do not stain well with Gram stain, other stains are preferable. The Giménez technique is used for *Rickettsia* species and Giemsa is used for *Orientia*. Rickettsiae can be grown in animals, including guinea pigs for *Rickettsiae* and mice for *Orientia*, as well as in embryonated eggs and cell cultures.

CLASSIFICATION

The genus *Rickettsia* was first divided into three different groups: spotted fever, typhus, and scrub typhus. *Rickettsia tsutsugamushi*, the agent of scrub typhus, has been found to be distinct enough by 16S rRNA gene sequence comparisons to warrant transfer into a new genus, *Orientia*, which was created to include the single species, *Orienta tsutsugamush* (Tamura et al. 1995). Presently, the genus *Rickettsia* is still made up of the typhus group (TG) and the spotted fever group (SFG). However, *R. canadensis*, which is transmitted by ticks and for which pathogenicity in man is unknown, along with *R. bellii*, does not belong to either of these groups. Several of the bacteria in these groups are pathogenic and are transmitted to man by arthropod bites or arthropod feces (Table 2). The TG includes *R. prowazekii*, the agent of the epidemic typhus, transmitted by the body louse, and *R. typhi*, the agent of murine typhus that is transmitted by fleas. The SFG includes an increasing number of serotypes following the improvement of approaches for rickettsial isolation and a more widespread interest in arthropod-transmitted disease (Raoult and Roux 1997). New SFG rickettsiae have been identified by culture or PCR from humans, including Israeli tick typhus rickettsia in Israel, Portugal, and Italy, *R. africae* in Africa, *R. japonica* in Japan, '*R. felis*' in Europe and America, the Astrakhan fever rickettsia in Russia, *R. honei* on Flinders' Island, Australia, and '*R. mongolotimonae*', *R. slovaca*, and *R. aeschlimannii* in France. Several rickettsia were isolated from ticks only: *R. massilliae* in France and in Greece, Bar 29 in Spain, *R. helvetica* in Europe and Japan, Strain S in Armenia, *R. peacockii*, '*R. cooleyi*,' and '*R. amblyommii*' in the USA, and *R. sibirica* HL-93 in China. Other rickettsiae were characterized in insects, but their culture has been impossible until now: AB bacterium, pea aphid rickettsia, and PTB bacterium were characterized in *Adalia bipunctata*, *Acythsiphon pisum*, and *Empoasca*

Table 2 *Classification of rickettsial strains*

Taxon	Vector	Geographic distribution
Spotted fever group		
R. conorii (malish)	*Rhipicephalus, Haemophysalis*	Mediterranean Sea, Black Sea, Africa

papaye, respectively (Raoult and Roux 1997; Parola and Raoult 2001; Roux and Raoult 1999).

PHENOTYPIC IDENTIFICATION AND CLASSIFICATION INSIDE THE GENUS *RICKETTSIA*

As rickettsiae are difficult to grow and purify, studies have been very limited. Until recently, rickettsial phylogeny was nonexistent and classification had been based on morphological, pathogenic, ecological, and antigenic criteria, as they could not be characterized by the phenotypic criteria traditionally used in bacterial taxonomy.

The differentiation of the groups within the genus *Rickettsia* has historically been based on several factors (Weiss and Moulder 1984): (1) the intracellular position in the nucleus and the cytoplasm for the SFG rickettsiae and *R. canadensis*, but only in the cytoplasm for *R. prowazekii* and *R. typhi*; (2) an optimal growth temperature of 32°C for the SFG (or 28°C for *R. felis*) and 37°C for the TG; (3) a G + C percent of DNA of 32–33

percent for the SFG and of 29–30 percent for the TG; (4) the cross-reaction of sera from patients with rickettsial infection with the somatic antigens of strains of *Proteus*, including OX19 for TG and *R. rickettsii* and OX2 for SFG. Serologic cross-reactions were also noted between the *R. canadensis* group and *R. prowazekii* and *R. typhi* on the one hand and between the representatives of the SFG on the other hand. Complement fixation was the first test used among SFG to differentiate between Mediterranean spotted fever and Rocky Mountain spotted fever (Plotz et al. 1944). *R. sibirica*, *R. akari*, and *R. australis* were then also differentiated (Pickens et al. 1965). Toxin neutralization tests were successfully applied to the differentiation of the same rickettsiae (Bell and Stoenner 1960). The advent of the density gradient centrifugation purification method enabled the separation of rickettsiae from host-cell component (Weiss et al. 1975) and has allowed the study of rickettsial proteins. Rickettsiae have been differentiated on the basis of their protein profiles in sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), including analysis of all rickettsia for which culture was possible. Western blot performed with antisera from convalescent humans or animals demonstrates reactivity with two proteins (now called rOmpA and rOmpB) for the SFG rickettsiae and *R. canadensis* and only with rOmpB for the TG rickettsiae. These outer-membrane proteins were shown to have molecular weights characteristic for each species (Gilmore and Hackstadt 1991). The indirect microimmunofluorescence (MIF) serologic typing test with mouse sera was developed in 1978 and was the reference method for the identification of new SFG rickettsiae for more than 10 years (Philip et al. 1978). The antigenic determinants for this serotyping scheme are rOmpA and rOmpB; two groups were confirmed, the TG, including *R. prowazekii*, *R. typhi*, and *R. canadensis*, and the SFG, in which ten serotypes were described. Two strains of *R. rickettsii*, Hlp-like and R-like, and isolates obtained from *Dermacentor occidentalis* in California clustered in the same serotype, but their antigenic profiles were different. Some antigenic relatedness among serotypes was identified. In one subgroup were included *R. sibirica*, *R. parkeri*, and *R. conorii*, which were found more distant. Another subgroup included *R. montanensis*, *R. australis*, and isolates obtained from *Ixodes pacificus* in Oregon, but these serotypes were only remotely related to one another. *R. rhipicephali* and *R. akari* did not clearly belong to any subgroup.

Anacker et al. (1987) demonstrated species, subspecies, and subgroup antigenic determinants on rOmpA and rOmpB by reactivity with monoclonal antibodies against *R. rickettsii*. Most of the species accepted by taxonomists could be differentiated, except for *R. akari* and *R. australis*, which reacted only with monoclonal antibodies to the group-specific lipopolysaccharide (LPS)-like antigen. Xu and Raoult (1998) determined taxonomic relationships among the SFG rickettsiae by comparative analysis of immunogenic epitopes reactive against a panel of 98 monoclonal antibodies. Monoclonal antibodies were directed against *R. africae*, *R. conorii*, *R. massiliae*, *R. akari*, *R. sibirica*, and *R. slovaca*. Neither monoclonal antibodies reactive with the LPS-like antigen nor those reactive with the major outer-membrane proteins reacted with *R. bellii*, confirming that this species is not an SFG rickettsiae. The taxonomic relationships determined among the SFG were consistent with those previously determined by genomic criteria, which are discussed below. Monoclonal antibodies also demonstrated that *R. felis* is antigenically related to SFG rickettsia (Fang and Raoult 2003).

Antibiotic susceptibility also allows differentiation of several groups. The rickettsiae of the *R. massiliae* group, of which *R. aeschlimanii* is a human pathogen (Raoult et al. 2002b), are resistant to erythromycin and rifampin. The other representatives of the genus *Rickettsia* are resistant to erythromycin and susceptible to rifampin (Rolain et al. 1998).

Considering modern biosystematics including phylogeny and population genetics, it is evident that the present classification and nomenclature of the genus *Rickettsia* are inadequate. The division of the genus in TG and SFG is not accurate based on gene phylogeny. *R. canadensis* and *R. bellii* should be excluded from the TG and the SFG, respectively.

Bacterial taxonomy should reflect classification and nomenclature of the different representatives and should allow identification of unknown organisms (Table 3). Polyphasic taxonomy, which integrates phenotypic and phylogenetic data, seems to be the best approach for rickettsial taxonomy, as demonstrated for other bacetrial genera (Vandamme et al. 1996). Serotyping by microimmunofluorescence and monoclonal antibodies are available. However, as these antibodies are often directed against rOmpA and rOmpB outer-membrane proteins, the information they give is redundant with those of genotypic approaches based on study *ompA* and *ompB* sequences, which are less subjective. Whole-cell protein patterns for the rickettsiae can be compared when culture is possible. Several methods should be considered. A standard definition determines that different strains belong to the same species if they share 70 percent or greater DNA–DNA relatedness (Wayne et al. 1987). However, the 70 percent cutoff value is not absolute. For rickettsia as an example, when applying this criterion, *R. rickettsii*, *R. conorii*, *R. sibirica*, and *R. monatensis* would be a single species (Walker 1989). An alternative phylogenetic species concept could delineate a species by comparison of percent gene similarities. The comparison of 16S rRNA sequences is not a good taxonomic approach for analysis of the genus *Rickettsia* because more than 97 percent similarity exists between any two taxa. However several other gene sequences have been determined for most species and

Table 3 *Genome size, G + C percent content, DNA–DNA homology, and antibiotic susceptibility for different representatives of the genus* Rickettsia

Representative	Genome size (kb)	G + C%	Erythromycin susceptibility	Rifampin susceptibility
R. conorii	1 237	32–33	R	S
R. rickettsii	1 272	32–33	R	S

R. typhi	1 099	29–30	S	S
R. canadensis	NT	29–30	R	S

NT, not tested; R, resistant; S, sensitive.

could be used to establish a method for rickettsial classification and nomenclature, including *ompA*, *ompB*, *gltA*, 17-kDa lipoprotein gene, and gene D (Sekeyova et al. 2001) (see Figure 1). Antibiotic susceptibility patterns also provide an interesting approach for confirming phylogenetic groups, as determined for rifampin resistance in the *R. massiliae* group. A remaining problem is that rickettsiae are intracellular bacteria, and for some, culture is not yet possible. Thus, for these bacteria, gene sequence comparisons are without doubt the only basis for taxonomy.

In conclusion, based on current knowledge, it is possible to differentiate four groups in the clade *Rickettsia–Orientia* (see Figure 1).

1. *Orienta*, the agent of Scrub typhus.
2. The typhus group with *R. prowazekii* and *R. typhi*.
3. The spotted fever group, which is very homogeneous with most of the agents of tick-borne rickettsioses (see Figure 2), including *R. rickettsii*, *R. sibirica*, *R. africae*, *R. conorii*, *R. slovaca*, *R. japonica*, *R. heilongjanghensis*, *R. honei*, and several independent species: *R. aeschlimanii*; *R. akari*, *R. australis*, and *R. helvetica*.
4. A fourth group, previously named the ancestral group (Fuerst and Poetter 1996), comprised of *R. canadensis* and *R. bellii*.

GENETICS

The annotated genome sequence of *R. prowazekii* was published in 1998 (Andersson et al. 1998) and that of *R. conorii* was published in 2001 (Ogata et al. 2001). Both have a single small unique chromosome, but each presents different features (see Table 4). The *R. prowazekii* genome not only is smaller, but also has a smaller coding content and a theoretical coding capacity that is only 61 percent of that of *R. conorii*. Rickettsial genomes also exhibit a previously unknown phenomenon called repeat parasitism, whereby palindromic repeats are inserted into various coding and noncoding regions. The predicted proteins encoded by the parasitized genes appear functional (Ogata et al. 2000). A comparative analysis of the two genomes shows that no gene was transferred since the separation of the two species, an estimated 80 million years ago. Moreover, the genomes express a perfect colinearity that allows an analysis of gene evolution. It was shown that some genes were progressively destroyed. First, a stop codon was insterted in the gene, but the two resulting open reading frames (ORF) were transcribed, them smaller ORFs (those with proteins predicted to be under 70 amino acids long) were no longer transcribed. These ORFs would then be degraded into noncoding remnants. Among the *R. conorii* genes in *R. prowazekii* genomes, 200 such remnants were identified.

Rickettsiae have paralog gene families that may transduce important functions. An ATP/ADP translocase gene is present in four copies and encodes a parasitic enzyme exclusively found among *Chlamydia*, *Rickettsia*, and plants. Four spotT copies are also found, which encode proteins that play a major role in processes related to bacterial starvation. Both rickettsiae also have several copies of genes encoding ProP, a transporter that plays a role in response to osmotic changes. Multiple genes of outer-membrane proteins of the Sca family

Table 4 *Comparison between* Rickettsia conorii *and* Rickettsia prowazekii

Species	*R. conorii*	*R. prowazekii*
Genome size (bp)	1 268 755	1 111 523
G + C content (%)	32.4	29.0
ORFs	1374	834
Coding content (%)	81	76

were found (five in *R. conorii* and four in *R. prowazekii*). Three of these proteins were previously identified as major antigens (rOmpA, rOmpB, and gene D).

METABOLISM AND COMPOSITION

Compared with bacteria that grow in axenic medium, little information is available about the metabolism of rickettsiae (Winkler 1990). *Rickettsia prowazekii* has been studied most extensively. ATP/ADP translocase, a unique parasitic enzyme, was identified that allows the importation of ATP from the host cytosol. Genome analysis predicts that several functions are missing (Ogata et al. 2001). For energy metabolism, *R. prowazekii* and *R. conorii* lack glycolysis, sugar nucleotide, and pentose phosphate pathways. For biosynthesis functions, both lack purine and pyrimidine ribonucleotide biosynthesis enzymes. Many amino acid biosynthetic pathways, and other gene families, including those for glutamate, serine, histidine, aromatic amino acid, and branched-chain amino acid biosynthesis, are lacking. Folic acid and cofactor enzymes, such as biotin and riboflavin (for *R. prowazekii* only) are also lacking.

The composition of the cell walls of rickettsiae is typical for that of proteobacteria (Winkler 1990), including peptidoglycan, lipopolysaccharide, and an outer membrane with only a few identified proteins. A family of 5 *Omp* (Sca family) has been identified by genome sequencing (Ogata et al. 2001). *sca5* encodes rOmpA and is present only in SFG rickettsiae; *sca4* encodes rOmpB and is present in SFG and TG but is absent in *R. bellii* and *R. canadensis*; *sca3* or gene D is also absent in the *R. bellii* group; and *sca1* and *sca2* have been detected in *R. conorii* and *R. prowazeki* (Ogata et al. 2001). These genes are also found in all other rickettsiae in a truncated form (unpublished). *rOmp*A and *rOmp*B are immunodominant proteins against which protective antibodies may be generated. As such, they are potential vaccines. Thus, OMPs determine the species-specific antigenicity and LPS determines the group-specific antigenicity.

Orientia tsutsugamushi does not exhibit a typical cell wall (Kawamura et al. 1995) and neither peptidoglycan nor LPS have been detected. One cross-reaction identified in *O. tsutsugamushi* is that used in the Weil–Felix test with *Proteus mirabilis* OXK.

PATHOGENICITY AND VIRULENCE FACTORS

The natural history of rickettsial diseases involves several steps (Walker et al. 2003). Transmission is provided by either saliva inoculation (tick-, mite-, or flea-transmitted), by autoinoculation after scratching lesions contaminated by insect feces (epidemic and murine typhus), or by aerosol (epidemic typhus by inhalation of louse feces, of other rickettsioses in the laboratory, or in the context of bioterrorism). After entry through the skin, mucous membranes, or lung, the rickettsiae will spread, usually through the lymphatics from the portal of entry. Target cells are the endothelial cells (with the exception of *R. akari* and *O. tsutsugamushi*, for which the monocyte is also a target). Rickettsiae enter host cells by phagocytosis. Adhesion may involve a rickettsial outer-membrane protein such as *rOmp*A and *rOmp* (Li and Walker 1998). After internalization, the phagocytic vacuole is rapidly lysed (Teysseire et al. 1995) and rickettsiae escape the phagocytic digestion to multiply freely in the cytoplasm (and the nucleus for spotted fever rickettsia). SFG rickettsiae can spread from cell to cell by actin mobilization (Teysseire et al. 1992; Heinzen et al. 1993). The infected cell is injured via lipid peroxidation of host-cell membranes (Silverman and Santucci 1988). In order to exploit the cell for its own growth, *R. rickettsii* inhibits cell apoptosis by upregulating NF-κB activation (Clifton et al. 1998). Escape from the vacuole is suspected to be mediated by an enzyme, and indirect evidence implicates a phospholipase A (Silverman and Santucci 1988; Walker et al. 2002). A gene encoding for a phospholipase D has been found in the genome of *R. prowazekii* and *R. conorii*, and preliminary data show that it may be a key factor in virulence (Renesto et al. 2003). The immune response to rickettsiae is mainly based on cytokine-mediated intracellular killing and clearance by cytotoxic CD8 lymphocyte (Feng and Walker 1996). In mice, interferon gamma (IFN-γ) and tumor neciosis fact alpha (TNF-α) synergistically activate nitric oxide synthase-2-dependent killing. Antibodies to outer-membrane proteins play a major role in protection against rickettsiae. The immune control of rickettsiae is not sterilizing. *R. prowazekii* survive in apparently cured patients who may relapse, years later, with the influence of stress. Persistence, late relapse, and chronic diseases have not been established for other rickettsioses.

TOOLS FOR THE DIAGNOSIS OF RICKETTSIOSES

The biological tools for diagnosis have changed significantly in recent years. The main difference comes from the application of molecular biology techniques, the generalized use of PCR amplification, and microcell culture using shell vial methodologies (Raoult and Roux 1997)

Isolation of Rickettsiae

Rickettsiae are typically identified with Giménez staining, although some other bacteria also retain the basic carbol fuchsin stain and must be distinguished on the basis of culture requirements. Rickettsiae have beenisolated by several different methods. Animal inocula-

tion has been widely used, originally with guinea pigs and subsequently using rats and voles. Embryonated eggs have also been widely used. However, cell culture is currently the most widely used system for primary isolation. Rickettsial cell culture isolation differs from that used for viral isolation, since antibiotics, with the exception of cotrimoxazole, cannot be used (Kelly et al. 1992). Tick or mammalian cell lines have been used. We have used a microculture system to isolate rickettsiae from human blood and other sources (Bacellar et al. 1995; Balayeva et al. 1994; Eremeeva et al. 1994; Marrero and Raoult 1989). The shell vial assay was adapted from a commercially available method for cytomegalovirus culture with early antigen detection. Isolation of rickettsiae by cell culture is now performed routinely in our laboratory using heparinized (leukocyte cell buffy coat) blood, skin biopsy samples before antibiotic therapy, or arthropods (Marrero and Raoult 1989; Espejo-Arenas and Raoult 1989). Many rickettsiae, including *R. conorii*, *R. rickettsii*, *R. massiliae*, *R. aeschlimannii*, *R. slovaca*, *R. helvetica*, '*R. mongolotimonae*,' and *R. africae*, have been isolated by this method. It has also been used in Zimbabwe (Kelly et al. 1992) and in Portugal (Bacellar et al. 1995). Although this assay is useful, for unknown reasons about one-third of the isolates are lost on passage (La Scola and Raoult 1996). However, the importance of culture cannot be underestimated, since obtaining an isolate from a tick or a patient is the ultimate goal in rickettsial disease description. Recently, we faced an unsolved problem in trying to grow *R. felis*. This rickettsia was reported to grow in Vero cells at 37°C (Radulovic et al. 1995) but was lost under these conditions. We were unable to grow it from infected fleas in our routine shell vial assay over a period of 1 year. After multiple attempts, we tried isolation of *R. felis* at 28°C, as its arthropod hosts are fleas (Raoult et al. 2001a). Flea-associated microorganisms, such as *Yersinia pestis*, frequently grow better at this temperature. As HEL cells do not grow well at 28°C, we used XTC2 cells, an amphibian cell line that grows well at 28°C and is used for arbovirus culture. This technique allowed easy isolation of *R. felis* (Raoult et al. 2001a). Subsequently, we tried without success to grow it at 37°C (La Scola et al. 2002). We believe that this organism does not grow at 37°C and that the first report of its cultivation reflected contamination by *R. typhi* (La Scola et al. 2002).

Currently, when an isolate has been obtained, the best method of identification is gene-based. Citrate synthase gene (*gltA*), the 16S rRNA gene, 17-kDa lipoprotein gene, and outer-membrane protein genes (*rOmpA*, rOmpB, and gene D) are most frequently used for this purpose (Raoult and Roux 1997). However, a clear genetic definition of a new species is currently lacking. Traditionally, the *Rickettsia* species definition was based on serotyping by microimmunofluorescence (MIF) (Sekeyova et al. 1998). This technique takes a long time, requires a pool of antisera, and lacks reproducibility.

Serology

Serological assays are the simplest diagnostic tests to perform. The Weil–Felix test was the first to be used and involves antigens from three *Proteus* strains: *P. vulgaris* OX2, *P. vulgaris* OX19, and *P. mirabilis* OXK. Its use in the diagnosis of rickettsioses is based on serological crossreactions (Raoult and Dasch 1995). The test lacks sensitivity and specificity but has historically been used for laboratory diagnosis and provides evidence of newly encountered rickettsioses.

Today, the most commonly used serological test is MIF. It is reliable but does not allow differentiation of infection among the SFG rickettsia (Hechemy et al. 1986; Hechemy and Michaelson 1985). The Western blot immunoassay (Raoult and Dasch 1995) allows differentiation among the SFG, provided that acute-phase sera are used. The test detects two types of antigens, high-molecular-weight outer-membrane protein (rOmpA and rOmpB) and LPS-like antigen. The high-molecular-weight outer-membrane proteins are species-specific (Beati et al. 1994; Raoult and Dasch 1995) and provide the basis for rickettsial serotyping (Philip et al. 1978). If sera are collected very early in infection, strong homologous reactions are often observed, making a specific diagnosis possible (Raoult et al. 2001c). However, as this rarely occurs, more specific methods are needed. Cross-absorption studies are useful, especially if complemented by Western blotting (Brouqui et al. 1997) (see Figure 3). This is the case for typhus, because in 50 percent of patients, serum antibody titers were the same when tested using *R. prowazekii* and *R. typhi* antigen (La Scola et al. 2000). Although this technique is accurate, it is also very expensive and time-consuming, since a large number of rickettsiae are required for each absorption (La Scola et al. 2000).

It must be emphasized that serological testing can be considered only the first step in diagnosis or in recognition of a rickettsial disease. In general, direct evidence of the identity of a rickettsial pathogen is required before purported new syndromes, new manifestations, or new areas of endemic infection can be defined. This evidence should be based on a combination of culture, microscopic, or genetic detection techniques and not solely on serology. In fact, the literature is replete with serologically based reports of new diseases or new clinical forms of disease that can only be viewed with some degree of skepticism (Raoult and Roux 1997). Recently, crossreactions were identified between *Legionella* and *Rickettsia* species (Raoult and Dasch 1995). In conclusion, MIF remains the basic technique. It is useful to test several antigens simultaneously to help identify the causative species, which usually exhibits a

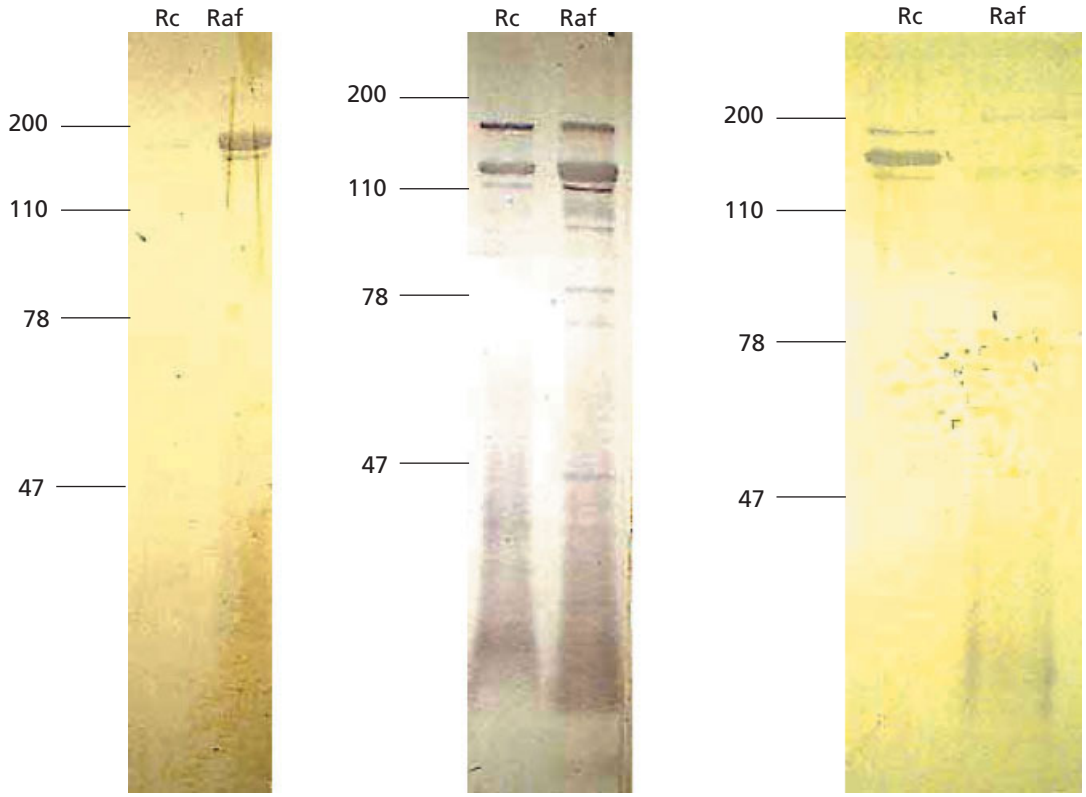

Figure 3 *Western blot comparing* Rickettsia conorii *and* Rickettsia africae.

higher titer. Determining the presence of IgM is useful to confirm recent infection. Usually, diagnostic cutoffs are 64 or 128 for IgG antibodies and 32 or 64 for IgM antibodies.

PCR-based detection of Rickettsiae

Rickettsiae may be detected by PCR amplification from blood, skin biopsy samples, and arthropod tissues. To preclude PCR inhibition and to enhance sensitivity, specific procedures must be used prior to amplification from blood. Cells are sedimented and the leukocytic cell buffy coat is used for rickettsial testing. Although heparinized blood is used for cell culture, it is preferable to use blood collected in ethylenediaminetetraacetic acid (EDTA) or sodium citrate, because heparin inhibits PCR and is difficult to neutralize. PCR amplification must be performed before initiation of antibiotic treatment and before antibody becomes detectable. Fresh tissues are preferred for this procedure, but paraffin-embedded tissues and even specimens fixed and mounted on to slides may be used (Stein and Raoult 1992). Although rarely present in Rocky Mountain spotted fever and not always present in other rickettsioses, the tâche noire (eschar) is the most useful biopsy sample to assay (Williams et al. 1994). Tâche noire samples are the best for detection of SFG rickettsiae because the tissue contains more bacteria than are present in blood; several isolates have been characterized by this approach (Brouqui et al. 1997; Raoult et al. 1996). PCR amplification of tâche noire or blood samples can be very useful because infection can be detected before cell culture is positive or seroconversion has occurred.

PCR-based methods for the detection of rickettsiae are attractive as they not only circumvent the need for culture but also possibly offer more sensitive and specific alternatives. Rickettsial DNA can also be detected in ticks (Gage et al. 1994; Gage et al. 1992), fleas, and lice by PCR-based amplification method (Higgins and Azad 1995). Detection strategies based on recognition of sequences within the 16S rRNA gene (Roux and Raoult 1995; Pretzman et al. 1995), and genes encoding the 17-kDa lipoprotein (Anderson and Tzianabos 1989; Baird et al. 1996; Balayeva et al. 1995), citrate synthase (Schriefer et al. 1994; Raoult et al. 1997; Wood et al. 1987), and rOmpB (Raoult et al. 1997; Gilmore et al. 1991) and rOmpA (for SFG rickettsiae (Raoult et al. 1996; Niebylski et al. 1997; Roux et al. 1996) outer-membrane proteins have been described. Since none of the PCR assays to date is specific for individual rickettsial species, reaction products must be further analyzed to identify the species being detected. Approaches involving either restriction endonuclease analysis or nucleotide sequence determination have been described.

The major problem when using PCR is the risk of contamination. To circumvent this problem, we sequence all amplicons and consider a diagnosis only when either the sequence is found for the first time in the laboratory or when at least two different target genes have been amplified and sequenced. Regardless, negative controls that mimic typical specimens should be used every third or fifth sample. Amplification should not be detected in any negative control before interpretation of results.

In order to increase the specificity of PCR, a new technique termed 'suicide PCR' was described. This technique was first introduced to detect *Y. pestis* in ancient remains (Raoult et al. 2000). In this technique, a target sequence is selected that has never before been used in the laboratory and is used for a single assay only. As no prior contamination is possible, highly sensitive techniques, such as nested PCR, are therefore applicable with limited risk. This technique has been used for the diagnosis of *R. africae* (Raoult et al. 2001b) and *R. slovaca* (Raoult et al. 2002a), which illustrates the greater robustness and potential than regular PCR. The availability of the complete genome sequences of *R. prowazekii* (Andersson et al. 1998) and *R. conorii* (Ogata et al. 2001) provides a large potential complement of target sequences for such studies.

Immunological detection of Rickettsiae

Skin biopsy specimens have been used in the diagnosis of rickettsioses since the early work of Woodward (Walker et al. 1978b; Woodward 1973). Samples can be tested as fresh frozen sections or after fixation and paraffin embedding. Clinical samples obtained at autopsy can be tested in the same manner as skin biopsy specimens (Walker et al. 1978a, 1981).

The use of methods incorporating specific polyclonal or monoclonal antibodies allows detection of rickettsiae in blood or tissue (George et al. 1992). This diagnostic approach allows the confirmation of infection in patients before seroconversion and permits rapid specific treatment. The method can also be used to diagnose rickettsial infection in fixed tissues retrospectively (Paddock et al. 2003).

Ticks collected for attempted isolation of Rickettsiae should be kept alive before being tested. If transport or long-term maintenance is needed, a humidified chamber is useful. While the ticks are still alive, the hemolymph test should be performed following surface sterilization (Burgdorfer 1970). In this procedure, one tick leg is amputated, allowing the collection of a drop of hemolymph, which can be applied on to a glass slide and subjected to either Giménez staining (Gimenez 1964) or immunodetection methods. Ticks should then be dissected (Kelly et al. 1991; Peter et al. 1990). Tick tissues, including the reproductive organs, can be carefully removed for further testing. Immunological detection methods can incorporate polyclonal or monoclonal antibodies, the latter of which can be used to determine the infecting species. Immunofluorescent labels have been widely used in conjunction with these antibodies, but immunoperoxidase labels and detection systems appear to allow a better microscopic definition of cells around the detected Rickettsiae (Dumler et al. 1990). *R. typhi* can also be detected in infected fleas by enzyme-linked immunosorbent assay (ELISA) (Dobson et al. 1989).

HABITAT AND EPIDEMIOLOGY

Rickettsiae live in association with arthropods (Rehacek and Tarasevich 1989). In some instances, this association is stable and the Rickettsiae are transmitted transovarially from the female to progeny. This is true for many tick-associated Rickettsiae, such as *O. tsutsugamushi* and *R. akari* in mites, and for *R. typhi* and *R. felis* in fleas. *R. prowazekii* kills its arthropod host and is not transmitted to its progeny (Houhamdi et al. 2002). The spectrum of possible infected artropods is not known. For example, human lice can be infected by *R. typhi* (Houhamdi et al. 2003), *R. akari* (Rehacek and Kovacova 1976), and *R. rickettsii* (unpublished data). Ticks can be artificially infected with *R. akari* (Rehacek and Kovacova 1976) and have been found naturally infected with *R. prowazeki* (Raoult and Roux 1997). Typically, there is a limit to the tick species that can harbor specific serotypes of Rickettsiae. However, specific coevolution of ticks and Rickettsiae has not been demonstrated. Some Rickettsiae (such as *R. rickettsii*) have a large range of hosts, whereas others are restricted to a single host.

The geographical and temporal distributions of rickettsioses and ehrlichioses are mainly determined by the distribution of their vectors (Table 2, Figure 4). Louse-transmitted diseases are found worldwide. The human louse is common to all humans. Lice parasitize poor people, preferentially in cold places, and specifically during times of war. Common fleas such as cat and dog fleas (*Ctenocephalides felis* and *C. canis*), as well as rat fleas (*Xenopsylla cheopis* and *Pulex irritans*), are distributed worldwide, as are the diseases (murine typhus and flea-borne spotted fever) caused by the Rickettsiae that they transmit. Tick species are highly dependent on the environment and very few are distributed worldwide, with the exception of *Rhipicephalus sanguineus*, the brown dog tick and vector of *Rickettsiae conorii* (in the old world). Therefore, tick-transmitted diseases are usually restricted to a part of the world where transmission by the local fauna is possible. For example, no SFG rickettsioses are currently found in either Europe or the USA.

Tick behavior may determine the target human population and seasonality of disease, as well as influencing the clinical presentation. For example, some *Derma-*

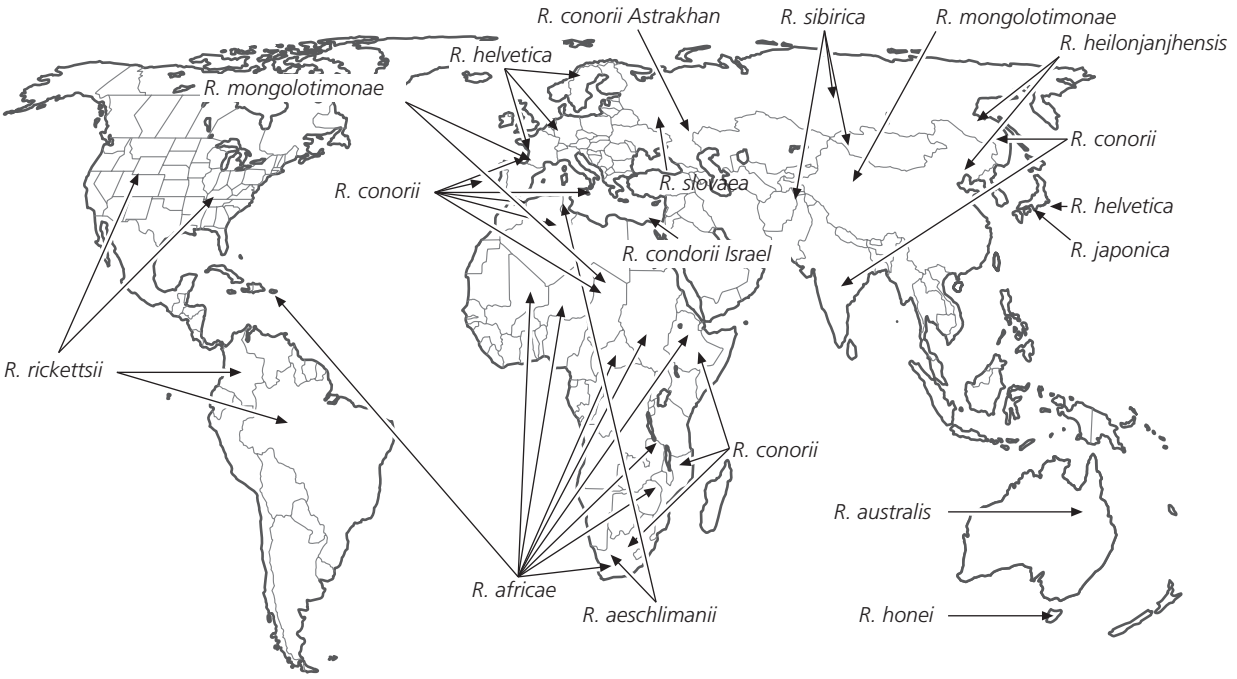

Figure 4 *Geographical distribution of tick-borne rickettsioses.*

centor species may wait for hosts with an ambush strategy, falling from as much as 1 m on to a hair-bearing host (Parola and Raoult 2001). Therefore, *Dermacentor* species frequently bite above the hairline and children are a primary target. As a consequence, *Dermacentor*-transmitted rickettsioses, such as Rocky Mountain spotted fever and infection by *R. slovaca*, more frequently involve children than do other rickettsial diseases (Raoult et al. 2002a). *Amblyomma* ticks are aggressive hunters that frequently attack in groups. This behavior may lead to grouped cases and detection of more than one inoculation eschar per patient. Wide variations in the annual incidence of tick-transmitted diseases such as Rocky Mountain spotted fever and Mediterranean spotted fever have been observed. A worldwide increase in the 1970s was noted, followed by a decrease in the 1980s that is not understood. Several hypotheses suggested such factors as increased exposure, better use of diagnostic tests, or a shift from effective to ineffective, empirically prescribed antibiotics (Walker and Raoult 1995) (see Table 5).

CLINICAL MANIFESTATIONS

Rocky Mountain spotted fever

Rocky Mountain spotted fever (Table 5) is the most severe of all rickettsioses. It is caused by *R. rickettsii* and is currently the only tick-transmitted rickettsiosis recognized in America, where it is prevalent in 44 US states and in Central and South America (Argentina, Brazil, Colombia, Costa Rica, Mexico, and Panama). The vectors are mainly *Dermacentor andersonii* (wood tick) in the western USA, *D. variabilis* (the American dog tick) in the eastern, southern, and Midwest USA, and *Amblyomma cajennense* in Central and South America (De Lemos et al. 2001; Sexton and Kaye 2002). There are 500–1 000 cases annually in the USA, with a majority diagnosed during late spring and summer (Paddock et al. 2002). The disease is relatively more prevalent in children under 10 years of age.

Rocky Mountain spotted fever starts with fever and headache after an incubation of 2–14 days. The fever is high and associated with nonspecific symptoms and signs including malaise, nausea, myalgias, anorexia, vomiting, and diarrhea. The classical triad of fever, headache, and rash is present in only 44 percent of confirmed cases. The rash is initially macular and appears first on the ankles and wrists and then becomes generalized. The rash can evolve from pink to petechial and purpuric. A rash can be absent, and 'spotless' fever represents 34 percent of cases.

The disease results to various degrees from increased vascular permeability in multiple organs that can lead to multiple organ dysfunction syndrome. In severe forms, patients suffer edema, hypovolemia, hypoalbuminemia, and hypotension, leading to shock. In these cases, necrosis and gangrene of the extremities can occur. In some instances, noncardiogenic pulmonary edema develops and causes death. Renal failure could result from hypovolemia and shock, or from acute tubular necrosis, and may require hemodialysis. Frequent neurological manifestations include confusion, lethargy, and

Table 5 *Main characteristic rickettsioses*

Bacteria	Disease	Rash	Specificity	Inoculation eschar	Multiple eschars	Draining lymph-adenopathy	Mortality (without treatment) (%)

R. felis	Flea-borne spotted fever	Yes	–	Yes	Possible	Maybe	?

stupor. Cerebrospinal fluid (CSF) exhibits pleocytosis, usually a few monocytic cells (10–100), indicative of meningitis in one-third of cases. Heart involvement can cause dysrhythmia. Liver involvement manifests as an increase in serum transaminases in one-third of patients and as jaundice in eight percent. The intestinal tract involvement manifests as abdominal pain, diarrhea, vomiting, and, in severe cases, bleeding (which can lead to death). Ocular involvement includes conjunctivitis and retinal abnormalities.

Laboratory examination reveals a normal number of white blood cells, but bands and immature myeloid cells are often observed. Thrombocytopenia is seen in 30–50 percent of cases and may be marked in severe disease. Anemia may develop. Coagulopathy with decreases in clotting factors (infrequently including fibrinogen), and prolonged coagulation times may contribute to bleeding; hypoalbuminemia may be present; and proteins of acute phase response increased (C-reactive protein, ferritin, fibrinogen). Hyponatremia and hypocalcemia may also be noted. Increased concentrations of serum enzymes such as aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT), lactate dehydrogenase, and creatine phosphokinase are common.

The evolution of Rocky Mountain spotted fever depends strongly on timing of diagnosis and antibiotic treatment. The spontaneous evolution is frequently fatal; the current fatality rate is 2.4 percent based on a 4-year national survey in USA (27 deaths were attributable to the disease during this period), but local figures may be considerably higher. Chloramphenicol is associated with a poorer outcome than doxycycline (Holman et al. 2001).

Other tick-borne rickettsioses

Rickettsia conorii (Table 5) causes Mediterranean spotted fever. The species comprises a group of different but closely related serotypes; the type strain is Malish. Other regional serotypes include Israel (in Israel and southern Europe), Astrakhan (in Russia), and Indian

tick typhus *Rickettsia* (in India) (Raoult and Roux 1997). Mediterranean spotted fever resembles Rocky Mountain spotted fever but is milder. A malignant form of the disease with a purpuric rash and shock has been described in alcoholic, diabetic, and elderly patients (Raoult et al. 1986). The typical clinical presentation is that of a patient with fever, rash, and tâche noire, a black eschar at the site of the tick bite. The tâche noire is found in 50–80 percent of cases. The rash is frequently papular, which led to one of the names of the disease, Boutonneuse fever. Israel spotted fever (Yagupsky and Wolach 1993) and Astrakhan fever (Tarasevich et al. 1991) appear milder than typical MSF, and tâche noire is frequently lacking.

R. africae, which causes African tick bite fever, may be responsible for the most frequent tick-borne rickettsiosis worldwide. The Rickettsiae are transmitted by the African ticks, *Amblyomma hebraeum* and *A. africanum*, which attack in groups and lead to a high prevalence of autochthonous infection in rural Africa and in travelers (Raoult et al. 2001b). The tick attacks typically generate grouped cases. In half of cases, more then one tâche noire is detected (see Figure 5). The disease is milder than Mediterranean spotted fever. Fever is frequently absent; a rash is observed in only one-half of the patients and may be vesicular. Tâches noire are frequently observed on lower limbs and are often associated with lymphadenopathy in the groin.

Japanese spotted fever (Mahara 1997), caused by *R. japonica*, and Siberian tick typhus, caused by *R. sibirica* (Rehacek and Tarasevich 1988), both resemble mediterranear spotted fever. *R. australis* (Queensland tick typhus) and *R. honei* (Flinders Island spotted fever) cause diseases resembling Mediterranean spotted fever, but the rash can be vesicular (Graves and Stenos 2003).

Figure 5 *Patient with* Rickettsia africae *infection. Note the presence of the two tâches noire.*

Infections caused by '*R. mongolotimonae*' resemble Mediterranean spotted fever, but in some cases exhibit specific clinical features characterized by tâche noire, groin lymphadenopathy, and draining lymphangitis (Fournier et al. 2000a). *R. slovaca* causes a disease apparently common in Europe (Hungary, France, Spain) (Raoult et al. 2002a), but is more prevalent in children and women, contrary to other tick-borne rickettsioses. It rarely produces exanthema, and the typical clinical picture includes an erythematous skin lesion at the site of the tick bite (usually in the scalp) and tender cervical lymphadenopathy. Residual alopecia can be observed at the site of the tick bite (see Figure 6). *R. aeschlimanii* infection resembles that caused by *R. conorii*. *R. heilongjiangensis* causes fever, rash, tâche noire, and draining, tender lymph nodes. It is prevalent in Siberia and China (unpublished data).

The diagnosis of Rocky Mountain spotted fever and other tick-borne rickettsioses is similar, using mainly serology indirect fluorescent antibody (IFA) and PCR or immunohistochemistry of skin lesions (see Tools for the diagnosis of rickettsioses), with the exception of *R. slovaca* infection, in which the serological response is weak (perhaps because of it lacks generalized infection) but may be diagnosed by PCR of skin lesions or lymph node aspirates (Raoult et al. 2002a).

Murine typhus

Humans often come into contact with rat fleas, which are distributed worldwide in domestic environments. Murine typhus is prevalent in hot and humid areas. In the USA, 50–100 cases are reported yearly, mainly in southern California and southern Texas. A transmission cycle also involving opossums and cat fleas (*C. felis*) has been demonstrated (Dumler et al. 1991).

The incubation period ranges from 8 to 16 days. The disease begins with abrupt fever, nausea, vomiting,

Figure 6 *Residual alopecia of a patient with* Rickettsia slovaca *infection.*

myalgias, arthralgias, and headache. A rash is observed in 40–50 percent of patients, on average 6 days after the onset. The rash consists of pink macules, which can evolve into a maculopapular rash (Tselentis et al. 1986) that does not involve the face, palms, or soles. In severe cases, it can become purpuric. Pneumonia can be observed in severe cases, and, when severe, respiratory distress can lead to intubation and artificial ventilation. Neurological symptoms range from confusion and stupor, to coma and seizures in severe forms. Cerebral hemorrhage may occur. Digestive tract involvement can manifest as vomiting, abdominal pains, jaundice, and, in severe cases, gastric hemorrhage (Table 5).

A moderate increase in serum liver enzymes is common. In patients with severe disease, hyponatremia and hypoalbuminemia are observed. The prognosis is usually favorable, but ten percent of patients require intensive care and one percent die.

Flea-borne spotted fever caused by *R. felis* is a new, incompletely defined disease. The bacterium is found in fleas in the USA, Peru, Europe, and Africa. Seven cases have been reported from Texas, Mexico, Brazil, France, and German (Raoult et al. 2001a; Richter et al. 2002; Zavala-Velasquez et al. 2000). All reported cases exhibited fever, a rash was detected in six out of seven, and an inoculation eschar was observed in some cases.

Epidemic louse-borne typhus

The human body louse lives in clothes and multiplies rapidly with cold weather and lack of hygiene. Their detection and prevalence reflects the low socioeconomic status of certain members of a society. Louse-borne typhus is prevalent during war, in poor countries, and even among the homeless populations of affluent societies, including those in the USA and Europe. An outbreak of typhus involving 100 000 people was reported in 1997 during the civil war in Burundi (Raoult et al. 1998), and cases were reported in Russia (Tarasevich et al. 1998), Peru (Raoult et al. 1999), USA, Algeria (Niang et al. 1999), and France (unpublished) in the 1990s (Raoult and Roux 1999). The epidemiology of *R. prowazekii* is mainly related to humans as reservoirs and lice as vectors. However, flying squirrels in the USA constitute a sylvatic reservoir and generate a few cases of typhus (Bozeman et al. 1975). The patient is usually contaminated by infected louse feces (in which *R. prowazekii* can survive for weeks) (Houhamdi et al. 2002), through aerosols, or by skin autoinoculation. Patients who recover from typhus may harbor the bacterium in a dormant form, leading to relapse years later. The relapsing form is named Brill–Zinsser disease (Stein et al. 1999). During the relapse, a bacteremia occurs, which may allow the start of a new outbreak if lice bite the patient.

Typhus (Table 5) begins abruptly with fever, headaches, and myalgias. Pneumonia is common. Neurological involvement manifests as stupor, confusion, or coma. A rash is observed in 20–80 percent of the patients and is more rarely observed on dark skin. It usually starts in the axilla and then spreads. It is macular and evolves to purpuric in severe cases. In some cases, diarrhea and jaundice are reported. Splenomegaly is infrequently found. In severe cases, shock is observed; the spontaneous fatality rate in the absence of specific antibiotic therapy is 20–30 percent.

Brill–Zinsser disease is milder and frequently undiagnosed, as the rash can be absent. The patient interview may reveal prior exposure to lice and a diagnosis of typhus years earlier.

Sylvatic typhus in the USA is caused by a variant *R. prowazekii* and is also milder. The most prominent clinical features are neurological. Only a few cases have been described and nearly all occurred in areas east of the Mississippi, where the eastern flying squirrel is found.

Rickettsialpox

Rickettsialpox (Table 5) is caused by *R. akari*, which is transmitted by mites of the house mouse (*Mus musculus*). After 7–10 days' incubation, fever, rash, and an inoculation lesion are observed. The local lesion may be vesicular or an eschar and is associated with tender, draining lymph nodes. The rash can also become vesicular (smallpox rickettsia was another name of *R. akari*). The disease is mild.

Scrub typhus

Scrub typhus is a common disease caused by *O. tsutsugamushi*. It is prevalent in eastern Asia and Oceania when chiggers (larval mites) are common (Kawamura et al. 1995). Local residents and tourists may be exposed to chigger bites. The real prevalence of scrub typhus is not known, but in Thailand, for example, it is with leptosporis one of the two most important causes of infection in hospitalized patients. During the Vietnam War, scrub typhus was a major cause of fever in American soldiers (Deller and Russell 1967; Berman et al. 1973). It is also common in India, but apparently grossly underreported (Mathai et al. in press).

The major symptoms of scrub typhus (Table 5) are fever, mental status changes, headache, inoculation eschar, and lymphodenopathy (Tattersall 1945; Berman and Kundin 1973). Ten or more days after exposure to a focus of scrub typhus, the disease onset is abrupt, with fever, headache, and myalgias. One or more inoculation eschars are found at the site of the mite bite in half of all cases (Kawamura et al. 1995). The rash is macular, pale, transient, and easily missed. Lymphadenopathy can

be tender and is sometimes limited to the site of the mite bite. Hepatomegaly, general lymphadenopathy, and splenomegaly can be observed. Mental changes are frequent and range from slight intellectual blunting to coma or mania (Tattersall 1945).

In severe cases, evolution to multiple organ dysfunction syndrome with hemorrhage can be observed. After apparent recovery and following short treatment courses, relapses frequently occur. Relapse disease is usually less severe than the first attack. Scrub typhus is associated with a reduction of viral load with human immunodeficiency virus (HIV-1)-infected patients and has been observed to restore the immune potential of infected patients (Watt et al. 2000b). There is a wide variation in prevalence of cutaneous symptoms as well in severity and fatality rate (Kawamura et al. 1995). Prevalence varies from 3 percent in Taiwan to 60 percent on the northern coast of Japan. Scrub typhus is still a life-threatening disease despite the availability of efficient treatment. During pregnancy, scrub typhus frequently causes abortion (Mathai et al. in press).

ANTIBIOTIC SUSCEPTIBILITY TESTING

Because of their obligate intracellular lifestyle, susceptibility of Rickettsiae to antibiotics cannot be assessed by conventional microbiologial tests (Parola et al. 2002; Raoult and Maurin 2002a, b; Maurin and Raoult 1998, 2002a, b; Walker and Sexton 2002).

Arthropod model

Infected body lice have been used in an in vivo model to test the antibiotic sucsceptibility of *R. prowazekii* to antibiotics. Lice usually die from infection with *R. prowazekii*. Infected lice received either doxycycline or ripamcin. For both antibiotics, inhibitions of rickettsial growth and a delay in death of infected body lice were obtained.

Embryonated egg model

In the embryonated egg model, Rickettsiae are injected into the yolk sacs of eggs. This results in death of the embryo after an interval of several days. Antibiotics are administered by the same route within the first hour following inoculation. Antibiotic activity is deduced based upon the differences in mean survival time of infected embryos that received antibiotics as compared with infected controls. By this method, and confirming with Giménez staining of yolk sacs, penicillin G and the aminoglycosides streptomycin and gentamicin are not effective. Oxytetracycline and, to a lesser extent, chlortetracycline and chloramphenicol, were considered rickettsiostatic. Erythromycin was found to be effective against *R. prowazekii*. However, Weiss and Dressler (1960) demonstrated that in vitro, *R. prowazekii* could become resistant to this antibiotic after only three passages.

Cell culture models

Plaque formation in infected cell cultures was first used for enumeration of viable Rickettsiae and was later adapted for the determination of in vitro antibiotic susceptibility. The plaque assay system is recommended. Cell monolayers (usually Vero cells) are grown in Petri dishes and are infected by incubation with a rickettsial inoculum while rocking to enhance Rickettsia–cell interactions. Infected cells are then overlaid with minimal Eagle medium (MEM) containing 2 percent fetal calf serum and 0.5 percent agar. Antibiotics are added at different concentrations at the same time, whereas no antibiotics are added in drug-free controls. The Petri dishes are incubated for 4 days at 37°C in a 5 percent CO_2 atmosphere, and the cell monolayers are then stained with neutral red dye allowing visualization of plaques. Minimum inhibitory concentrations (MIC) are defined as the lowest antibiotic concentration allowing complete inhibition of plaque formation, as compared with the drug-free control. Ives et al. recently described a new cell culture system in which inhibition of rickettsia proliferation by antibiotics was determined by comparing rickettsial growth in infected Vero cell cultures incubated in the presence of antibiotics to that in drug-free control (Ives et al. 1997). Infected cells were enumerated by indirect fluorescent antibody tests. Kelly et al. (1995) reported the use of flow cytometry to quantify the antibiotic susceptibility of *O. tsutsugamushi*. We have reported the more rapid and efficient measurement of rickettsial DNA concentrations by real-time quantitative PCR using a Light Cycler to evaluate rickettsial growth inhibition by antibiotics (Rolain et al. 2002).

Chloramphenicol, doxycycline, tetracycline, minocycline, and rifampin are effective against *R. rickettsii*, with MICs ranging from 0.005 to 1 μg/ml (see Table 6). Penicillins and cephems were considered poorly effective, although in earlier experiments, Wisseman et al. demonstrated partial inhibition of rickettsial growth and spheroplast-like rickettsiae when using high doses of penicillin (Wisseman et al. 1974). The newer macrolide compounds, roxithromycin, azithromycin, and clarithromycin, have been tested in the immunofluorescent antibody assay (Ives et al. 1997). Clarythromycin was the most effective compound, with MICs ten times lower than that of *erythromycin* (0.25 and 2 μg/ml, respectively). The new ketolide compound, telithromycin, displayed an MIC of 0.5 μg/ml. Nalidixic acid produces only partial inhibition of plaque formation by *R. prowazekii*, whereas the fluoroquinolone compounds were more effective. In vitro, quinolones are poorly effective on *R. tsutsugamush* (Kawamura et al. 1995). A preli-

Table 6 *Antibiotic susceptibility of rickettsiae to antibiotics minimum inhibitory concentrations (MIC) in μg/ml) (based on Rolain et al. 1998, 2000, 2002; Kelly et al. 1995; Watt et al. 1999)*

	Spotted fever group rickettsiae	*R. aeschlimanii*	Typhus group rickettsiae	*O. tsutsugamushi*
Doxycycline	0.06–0.25	0.06–0.25	0.06–0.125	0.02–0.9
Thiamphenicol	0.5–4	0.5–2	1-2	0.2–0.4
Rifampin	0.03–1	2–4	0.06–0.25	0.06
Erythromycin	2–8	1.8	0.125–1	>8
Clarithromycin	0.5–4	0.5–2	0.5–1	
Telithromycin	0.5–1	–	0.5	
Ciprofloxacin	0.25–1	0.25–1	0.5–1	6–24
Ofloxacin	0.5–2	0.5–1	1	3–24

minary report claimed that fluoroquinolones were effective in a mouse model, but this has not been confirmed. Moreover, ciprofloxacin is not effective in treating patients with scrub typhus (Mathai et al. in press). Azithromycin was effective for scrub typhus in a mouse model (Watt et al. 1999). Many new macrolide compounds exhibit very good in vitro efficacy and should be tested to find alternatives for doxycycline.

TREATMENT

Doxycycline is the drug of choice for the treatment of the rickettsioses. It was demonstrated that a single dose cured patients suffering from epidemic typhus and Mediterranean spotted fever. For other rickettsial diseases, a 7–14-day regimen is recommended. For children, doxycycline should also be used. It has been demonstrated that staining of teeth is unlikely to appear when fewer than five therapeutic courses of doxycycline are prescribed in childhood (Fort and Benincovi 1969). Chloramphenicol is an alternative treatment to doxycycline in pregnancy (Watt et al. 1996) and in people with tetracycline hypersensitivity. It is less efficient than doxycycline in treating Rocky Mountain spotted fever (Walker and Sexton 2002).

Macrolide antibiotics have been tested for treatment of rickettsial diseases. Erythromycin should be avoided as it is ineffective for treatment of typhus and spotted fever (Maurin and Raoult 2002a). Clarithromycin (Cascio et al. 2001), azithromycin (Meloni and Meloni 1996; Cascio et al. 2002), and josamycin (Bella et al. 1990) were reported effective in the treatment of Mediterranean spotted fever. Azithromycin was also used with success for scrub typhus (Choi and Pai 1998). Macrolides can be used in pregnant women.

Rifampicin theoretically offers an alternative to doxycycline as MICs are low, except for *R. aeschlimanii*. However, a randomized trial performed in children suffering Mediterranean spotted fever showed that it was less efficient than doxycycline (Bella et al. 1991). Rifampin was shown to be effective in treating scrub typhus and should be recommended in pregnant women or in patients potentially infected with doxycycline-resistant strains (Watt et al. 2000a).

Quinolones exhibit some activity on Rickettsiae. Their use was proposed for the treatment of Mediterranean spotted fever (Gudiol et al. 1989) but should be avoided for treatment of typhus as a patient receiving ciprofloxacin died (Zanetti et al. 1998). In vitro results for *O. tsutsugamushi* are discrepant, but treatment failures for scrub typhus in pregnant women have been reported (Mathai et al. in press).

In conclusion, doxycycline currently remains the drug of choice for the rickettsioses. New macrolide compounds, such as telithromycin, that show great in vitro activity should be evalutated as alternative drugs.

INTRODUCTION

In the past, the taxonomy of the rickettsiae and what were broadly known as ehrlichiae was based principally on comparisons of phenotypic characteristics. More so than in other bacteria, historical, geographical, and environmental considerations also played important roles in classification. More recently, classification of rickettsiae and ehrlichiae has been based increasingly on DNA sequences, particularly on *rrs* (16S rRNA) and *groEL* gene sequence comparisons. As a result of genetic analyses, a realignment of the families *Rickettsiaeceae* and *Anaplasmataceae* was recently proposed (Dumler et al. 2001). The new classification schema eliminates the tribe structure of the *Rickettsiaceae* family by moving the remaining members of the prior tribe *Ehrlichieae* and placing them into the family *Anaplasmataceae*. The genetic analyses also revealed misalignment among the existing genera in the previous tribe *Ehrlichieae*, such that some members of the genera *Ehrlichia* and *Cowdria* were reassigned to other genera in *Anaplasmataceae*, with the creation of several new genus and species combinations. The final result of the realignment was the inclusion of four genera in the family *Anaplasmataceae*: *Anaplasma*, *Ehrlichia*, *Wolbachia*, and *Neorickettsia*; the genus *Cowdria* was eliminated and its sole species, *C. ruminantium*, was reassigned into the genus *Ehrlichia* as *E. ruminantium* nov. comb. Prior members of the genus *Wolbachia*, *W. persica* and *W. melophagi*, were reassigned on the basis of DNA sequence comparisons into the genera *Francisella* and *Bartonella*, respectively. The genera *Haemobartonella* and *Eperythrozoon* formerly assigned within the *Anaplasmataceae* were reassigned to the *Mollicutes* (mycoplasmas). *Aegyptianella* spp. that infect avian, reptile, and amphibian erythrocytes are likely to be species in the genus *Anaplasma*, but more study is needed. The common underlying nongenetic characteristic of the *Anaplasmataceae* is that the bacteria reside within a vacuole in the cytoplasm of the infected host cell, and that host cells generally involve both arthropod cells and mammalian cells of hematopoitic origin, except for some *Wolbachia* that reside exclusively in insect cells, and some *Wolbachia* and *Neorickettsia* that may also involve cells in helminths, including nematodes and trematodes, respectively. Pathogens of mammalian cells are found in the genera *Anaplasma*, *Ehrlichia*, and *Neorickettsia*, although a role for *Wolbachia* spp. in human

pathogenicity is becoming increasingly appreciated. The general properties of *Anaplasmataceae* that infect mammalian cells are presented in Table 1.

HISTORICAL PERSPECTIVES

Some of the *Anaplasmataceae* are very important pathogens of man and animals. At the time when Howard Taylor Ricketts was conducting his ground-breaking working on the 'virus' of Rocky Mountain spotted fever in Montana of the USA, Sir Arnold Theiler was describing small darkly stained structures, marginal points, near the edges of erythrocytes from cattle with redwater, a febrile hemolytic disease first identified in tick-exposed South African cattle. He reasoned that these marginal points were nondescript parasites that infected erythrocytes as did *Plasmodium* spp., as was the prevailing view in his day, and coined the name

Table 1 *Diseases and habitats of species of the ehrlichias*

Genetic group species	Animals affected	Disease	Invertebrate host	Geographical distribution
Anaplasma				
Anaplasma phagocytophilum	Humans, horses, dogs, ruminants, llamas	Tick-borne fever (ruminants), anaplasmosis (humans); formerly granulocytic ehrlichiosis (HGE, equine granulocytic ehrlichiosis)	Ticks (*Ixodes persulcatus* group, including *I. scapularis*, *I. pacificus*, *I. ricinus*, *I. persulcatus*, *I. spinipalpus*, and *I. trianguliceps*)	North and South America, Europe, Asia, Africa
Anaplasma platys	Dogs	Canine cyclic thrombocytopenia	Ticks?	North and South America, Asia, Europe, Australia
Anaplasma bovis	Cattle	Bovine ehrlichiosis	Ticks (*Hyalomma*)	Africa, Middle East, Europe, North America?
Anaplasma marginale	Cattle	Anaplasmosis	Ticks (*Dermacentor*, *Boophilus*), tabanid flies	Worldwide
Ehrlichia				
Ehrlichia canis	Dogs, humans	Canine monocytic ehrlichiosis, tropical canine pantocytopenia	Ticks (*Rhipicephalus sanguineus*)	Worldwide
Ehrlichia chaffeensis	Humans, dogs	Human monocytic ehrlichiosis	Ticks (*Amblyomma americanum*)	USA, Asia?
Ehrlichia ewingii	Dogs, humans	Canine granulocytic ehrlichiosis, ehrlichiosis 'ewingii'	Ticks (*Amblyomma americanum*)	USA
Ehrlichia muris	Mice	Unnamed	?	Japan
Ehrlichia ruminantium	Ruminants	Heartwater	Ticks (*Amblyomma hebraeum*)	Sub-Saharan Africa, Carribean Islands
Neorickettsia				
Neorickettsia sennetsu	Humans	Sennetsu ehrlichiosis	Fluke?	Japan, Malaysia
Neorickettsia risticii	Horses	Potomac horse fever, equine monocytic ehrlichiosis	Trematode (*Juga* spp.) cercaria, aquatic insects	USA, Europe
Neorickettsia helminthoeca	Dogs	Salmon poisoning, Elokomin fluke fever	Fluke (*Nanophyetus salmincola*)	Pacific northwest of North America
SF agent	Humans, dogs	Hyuganetsu disease	Fluke (*Stallantchasmus falcatus*)	Japan
Wolbachia				
Wolbachia pipientis-like symbionts	Arthropods, isopods	Cytoplasmic incompatibility, sex-ratio distortion	Seven orders of insects, *Armadillium*	Europe, USA
Wolbachia pipientis-like symbionts	Humans?	Contributes to inflammation with lymphatic filariasis?	Filarial nematodes	Tropical areas

HGE, human granulocytic ehrlichiosis.

Anaplasma marginale. Similar inclusions in febrile animals that were located within central regions of erythrocytes were denoted as *Anaplasma centrale*, although he was unable to discern other differences. By 1925, Cowdry had described the bont tick (*Amblyomma hebraeum*)-transmitted rickettsial agent of heartwater, a severe bovine illness in sub-Saharan Africa characterized by encephalitis and cardiac tamponade, and called it *Rickettsia ruminantium*. Tick-borne fever, a febrile condition of ruminants in Europe that was associated with multiple secondary infections, was described in 1932 and Gordon et al. implied a rickettsial agent as its cause before the name *Rickettsia phagocytophila* was eventually settled on in 1940. While this was occurring, Donatien and Lestoquard described several unique rickettsial infections of dogs and cattle in Algeria in 1936, and named them *Rickettsia canis* and *Rickettsia bovis*, respectively. The same year, Hertig named small bacteria in insect tissues as *Wolbachia*, in honor of S. Burt Wolbach, the pathologist who first demonstrated rickettsiae in tissues from infected patients. In 1938, Tyzzer described a parasite of blood neutrophils in North American *Microtus* and *Peromyscus* spp. that probably represented the same agent identified by Gordon in 1932; named this *Cytoecetes microti*, a genus name still preferred by some in the field. In the cumbersome task of taxonomic classification, Moshkovski recalled the early work of Kurlov, a Russian scientist working under the direction of Paul Ehrlich at the beginning of modern microbiology. Kurlov was assigned to study the causes of anemia in guinea pigs by examination of stained blood films. Although well recognized as noninfectious now, the Kurlov body was sufficiently similar in morphology to the intracytoplasmic inclusions seen with many of these infections that Moshkovski created a new genus in honor of Ehrlich, and assigned into it many of the species once classified as *Rickettsia*, to create the new combinations *Ehrlichia canis*, *Ehrlichia phagocytophila*, and *Ehrlichia bovis*; he also created the new genus *Cowdria* to accommodate the former *Rickettsia ruminantium*. Philip in 1953, and Misao and Kobayshi in 1954, described unique rickettsial species of dogs and humans that did not have strong tick or arthropod associations but in fact had closer epidemiological ties with the consumption of raw fish and, in the case of *Neorickettsia helminthoeca*, with trematodes that infest the fish and are consumed by the dog. Subsequent discoveries were classified as *Ehrlichia* spp. if the bacteria clustered in a vacuole in a peripheral blood leukocyte (*Ehrlichia equi* (Stannard et al. 1969), *Ehrlichia platys* (French and Harvey 1983), *Ehrlichia risticii* (Holland et al. 1985), *Ehrlichia chaffeensis* (Anderson et al. 1991), *Ehrlichia ewingii* (Anderson et al. 1992b), and *Ehrlichia muris* (Wen et al. 1995a), among others). A reclassification proposal in 2001 (Dumler et al. 2001) established the existing taxonomic structure and new combinations.

HABITAT

A common feature of the habitat of the pathogenic *Ehrlichia* and *Anaplasma* spp. is the association with ticks and vertebrate animals. Humans and some animals are accidental hosts that then develop clinical signs; such findings suggest that coevolution has permitted persistent infections in some reservoir hosts that do not result in clinical manifestations or signs of disease, such as with some cervids or small mammals. There are, however, considerable differences in the details of such associations, and each species (or groups of closely related species) needs to be discussed separately (Table 1).

Various microorganisms living in intracellular symbioses with arthropods cause sex-ratio distortion and alteration of sex determination of their hosts, such as parthenogenesis, female-biased sex ratios, and sterility of offspring of crosses between infected males and uninfected females. Most such microorganisms are relatives of the species *W. pipientis* (Werren et al. 1995). Hertig first described this species in 1936 as occurring in the gonads and gut epithelium of the mosquito *Culex pipiens*. Some *Wolbachia* spp. identified in filarial nematodes may influence successful development between larval instar stages and maturation into adults. The presence of *Wolbachia* bacterial components in the filariae is also suspected to contribute to a pro-inflammatory response that could exacerbate lymphatic or venous obstruction, or contribute to the post-inflammatory fibrosis that complicates filariasis (Taylor 2002).

A common feature of the tick-associated *Ehrlichia* and *Anaplasma* species is the inefficient transmission from one generation of ticks to the next. This ineffective transovarial transmission implies a reliance on horizontal transmission (tick–vertebrate host–tick) that further suggests the need for persistent infection, probably persistent bacteremia, of reservoir host vertebrates.

E. canis, a worldwide pathogen of dogs, is transmitted by the brown dog tick, *R. sanguineus*. Similarly, *A. variegatum* and *A. hebraeum* ticks transmit *Ehrlichia ruminantium* to ruminants. *E. chaffeensis*, which occurs most frequently in southeastern and south-central USA, and *Ehrlichia ewingii*, a human and canine pathogen also in the midwest USA, have been shown to occur in the tick vector, *Amblyomma americanum* (Lockhart et al. 1996). These two species may be difficult to differentiate by serological analysis, which has shown evidence of human infection in Europe, Asia, and Africa (Dumler and Bakken 1995). The former species *Ehrlichia phagocytophila*, *Ehrlichia equi*, and the unnamed agent of human granulocytic ehrlichiosis (HGE) have been combined into a single species, *Anaplasma phagocytophilum* that is responsible for human anaplasmosis (formerly HGE) in the northern USA and Europe; *Ixodes persulcatus* group ticks including *I. scapularis* in the eastern USA,

I. pacificus in the western US, *I. ricinus* in Europe and Asia, and *I. persulcatus* in Asia transmit the bacterium. Other tick hosts that do not bite man, such as *I. spinipalpis*, may also transmit *A. phagocytophilum* among small mammals and other animals (Richter et al. 1996). The habitats of other *Anaplasmataceae* are not well understood or studied. For *Neorickettsia*, ticks are not part of the transmission cycle, and fluke transmission has been proven for *N. helminthoeca*, *N. risticii*, and the *Neorickettsia* sp. in *Stellantchasmus falcatus* (SF agent) (Wen et al. 1996) and is suspected in the case of *N. sennetsu*. An important role exists for trematode metacercariae, which carry *N. risticii* to aquatic insects that are accidentally ingested; the importance of this cycle for other *Neorickettsia* spp. has not been evaluated.

MICROENVIRONMENT AND MORPHOLOGY

Species of the genera *Ehrlichia*, *Anaplasma*, and *Neorickettsia* prevent phagosome fusion with lysosomes and thus remain in a favorable environment for growth. A few species, such as *A. phagocytophilum*, *E. ewingii*, and *E. ruminantium*, invade and propagate in granulocytes, a biological niche unique among all bacteria, while *Anaplasma marginale* and *Anaplasma platys* grow within erythrocyte and platelet vacuoles, respectively. *Ehrlichia ruminantium* parasitizes predominantly endothelial cells in vivo, whereas in vitro it grows well in macrophage cultures. Similarly, *E. chaffeensis* may be propagated in a variety of cell lines, including macrophages, endothelial cells, and even fibroblasts.

The mechanisms by which vacuoles that contain *Anaplasmataceae* avoid fusion with lysosomes have been studied only for *N. risticii* (Rikihisa 1991a), *N. sennetsu* (Barnewall et al. 1999), *A. phagocytophilum* (Barnewall et al. 1999; Webster et al. 1998), and *E. chaffeensis* (Barnewall et al. 1997). All three of these species enter early endosomes; the vacuoles that contain *A. phagocytophilum* do not mature or accumulate additional markers of endosomes, whereas both *E. chaffeensis* and *N. sennetsu* accumulate other markers of early endosomes but never mature into later stages such as sorting or late endosomes or phagolysosomes (Barnewall et al. 1997; Webster et al. 1998). *E. chaffeensis* specifically abrogates vacuolar maturation by directing the accumulation of all cellular transferrin receptors to the parasitophorous vacuole. The net result is the shuttling of the infected vacuole into a receptor-salvage/recycling pathway that does not fuse with lysosomes.

Infection of canine monocytes with *Ehrlichia*, *Anaplasma*, and *Neorickettsia* spp. is effected by small round bacteria 0.5 μm in diameter. Upon entry into the vacuole, they increase in size and divide by binary fission to form clusters in a membrane-bound vacuole, usually referred to as morulae. Individual bacteria have typical gram-negative trilaminar outer and inner membranes. The various genera and species of *Anaplasmataceae* vary in the size of the morulae, some ultrastructural features, and time of release of the individual bacteria (Chaichanasiriwithaya et al. 1994; Popov et al. 1995). The morphology of ehrlichial morulae and individual bacteria is illustrated in Figure 1. Two distinct ultrastructural morphologies have been identified, including small cells with densely packed chromatin (dense core) and larger forms with loose, reticulated chromatin (reticulate). Despite the similarity to the life-stage forms of chlamydiae, both dense-core and reticulate forms divide by binary fission, although some evidence suggests that dense-core cells selectively express adhesins for binding to cells prior to internalization (Popov et al. 2000).

Anaplasmataceae bacteria vary from 0.2 to 1.5 μm in diameter and usually are coccoid or ellipsoid in shape, although a variety of unusual shapes and forms may be observed. Flagella and pili are not present; in vitro genetic recombination has not been demonstrated, although natural recombination of certain antigen encoding genes is probably a critical factor for prolonged in vivo survival in vertebrate reservoirs. Ultrastructural studies confirm that members of the genera *Ehrlichia*, *Anaplasma*, *Wolbachia*, and *Neorickettsia* contain chromosomal structures, ribosomes, and other subcellular organelles (Popov et al. 1995). As in the *Rickettsiaeceae*, bacteria in the family *Anaplasmataceae* are surrounded by an outer envelope (cell wall) similar to that of gram-negative bacteria. In general, both the inner and the outer leaflets have similar dimensions, unlike the situation for *Rickettsiaceae*. Moreover, lipopolysaccharide (LPS) is not present in *Anaplasmataceae*, although spheroplasts form in the presence of some antibiotics that target peptidoglycan, suggesting its presence in the cell wall (Rikihisa 1991a; Lin and Rikihisa, 2003). In some preparations, extensions of the bacterial membrane may allow the bacteria to become wrapped in several layers or to develop invaginations into the bacterial protoplasm (Popov et al. 1995). *Ehrlichia* spp. but not *Anaplasma* spp. possess intravacuolar fibrillar and tubular structures that may contain bacterial antigens. Some strains of *A. marginale* possess appendages extending from the surface of the endocytic vacuole into the host cell cytoplasm that also integrate bacterial antigens.

STAINING PROCEDURES

Romanowsky stains, such as Giemsa or Wright, or rapid methods are used frequently for light-microscopic visualization of *Anaplasmataceae*. Using this method, the microorganisms are easily recognized in tissue culture cells or blood smears, although the abundance of other intracellular granules and structures renders this less useful for histological sections. Acridine orange staining combines visualization with an assessment of physiological activity because active, but not dead, micro-

organisms, fluoresce an intense bright orange to red color against a yellow-green background. An ultraviolet microscope is required for this procedure, which will also stain most other bacteria and eukaryotes. Fluorescent antibody tests permit simultaneous detection and identification of the rickettsiae, depending in part upon the specificity of the antibody reagents used. *Ehrlichia* and *Anaplasma* cells have also been visualized in tissue sections by immunohistochemical methods that employ specific antibodies and by methods that use the in situ hybridization of specific nucleic acid probes (Dumler et al. 1991; Walker and Dumler 1997; Dawson et al. 2001).

LABORATORY ISOLATION, CULTURAL CHARACTERISTICS, AND GROWTH REQUIREMENTS

Of the classical methods for recovery of rickettsiae from clinical and environmental samples, the most successful for recovery of *Ehrlichia*, *Anaplasma*, *Wolbachia*, and *Neorickettsia* spp. is cell culture. Many species have not yet been propagated in vitro and depend upon propagation by continuous inoculation of infectious materials, usually blood, into susceptible animals. Moreover, *Wolbachia* spp. are particularly recalcitrant to in vitro growth as a lytic phase in rarely observed. A further difficulty in dealing with *Anaplasmataceae* is the inherent difficulty in deriving clonal populations, as monolayer plaques are not produced or are inapparent. *Ehrlichia*, *Anaplasma*, and *Neorickettsia* spp. have been grown in a variety of cells, including L929, BGM, mouse embryo, Vero, P388D1, DH82, bovine endothelial, tick embryo IDE8, HL-60 human promyelocytic leukemia, THP-1 human myelomonocytic leukemia, KG-1 human granulocytic leukemia, and mouse M1 myeloid leukemia cells, and in co-cultures of erythrocytes and endothelial cells (Rikihisa 1991a; Chen et al. 1995; Goodman et al. 1996; Wen et al. 1996). *Wolbachia pipientis*-infected mosquito cell cultures are available for study, and methods for infection of other cells have been described (O'Neill et al. 1997; Fenollar et al. 2003).

REPLICATION

Replication of *Ehrlichia*, *Anaplasma*, *Wolbachia*, and *Neorickettsia* spp. occurs by binary fission within the endosome. Although both dense-core and reticulate forms may divide, dense-core forms seem to predominate late in infection, suggesting a role in infectivity, perhaps owing to an enrichment in adhesins that facilitate entry into new host cells after discharge from the infected cell. Host cells infected with *Anaplasmataceae* show little cytopathology until cytoplasmic vacuoles are filled with microorganisms and the cells burst or the infected vacuole fuses to the cell membrane in an exocytic-like event.

METABOLISM

Limited information is available on the metabolism of *E. sennetsu* and *E. risticii* (Weiss et al. 1989). Isolated ehrlichiae resemble rickettsiae in being nonglycolytic and in carrying out oxidative phosphorylation and adenosine triphosphate (ATP) synthesis in the presence of citric-acid-cycle intermediates, particularly glutamine, when incubated at neutral pH. The genomic sequences of strains of *Ehrlichia chaffeensis*, *Ehrlichia ruminantium*, *Anaplasma phagocytophilum*, *Anaplasma marginale*, *Neorickettsia sennetsu*, and *Wolbachia* spp. are nearing completion and should allow a comprehensive overview of metabolic pathways among these bacteria.

CLASSIFICATION

Classification of rickettsiae has undergone significant change since publication of the last edition of *Bergey's Manual of Systematic Bacteriology* (Krieg and Holt 1984). In the newest edition (Garrity et al. 2005), the family *Rickettsiaceae* has been limited by reassignment of the genera *Ehrlichia*, *Neorickettsia*, *Cowdria*, and *Wolbachia* into the family *Anaplasmataceae*, also eliminating the tribe schema. In the reclassification, several new genus and species combinations were created, and additional members of *Anaplasmataceae* (the genera *Haemobartonella* and *Eperythrozoon*) were reclassified into the *Mollicutes*. The taxonomic standing of some genera such as *Aegyptianella* is still unresolved, although recent data suggest correct placement in the *Anaplasmataceae* family and a close relationship to the genus *Anaplasma* (Rikihisa et al. 2003). A current phylodendrogram based upon neighbor-joining analysis of informative positions of 16S ribosomal RNA genes of recognized species of *Anaplasmataceae* and their relationship to some *Rickettsia* species and *Escherichia coli* as an outgroup is shown in Figure 2. Similar trees result from the analysis of sequences of both *groESL* and *gltA* (citrate synthase) (Dumler et al. 2001; Sumner et al. 1997; Inokuma et al. 2002). Some authors suggest alternative classification; thus, the final schema has not yet been decided (Uilenberg et al. 2004).

GENOME

Increasing information about the genomes and genomic structure of the *Anaplasmataceae* is becoming available. The sizes of the genomes in this family vary from small for *Neorickettsia* (860–900 kbp), to moderate for *Ehrlichia chaffeensis* (1236 kbp), *Anaplasma marginale* (1250 kbp), and *Anaplasma phagocytophilum* (1580 kbp), and highly variable for *Wolbachia* spp. (950–1660 kbp). Similarly, the %G + C varies from very low (32–39 percent) for *Ehrlichia* spp. to high (56 percent) for *Anaplasma marginale* (Alleman et al. 1993). The molecular differentiation of *Anaplasmataceae* depends primarily on sequences of *rrs* (16S rRNA) and *groEL* genes (Dumler et al. 2001). Whereas new isolates and molecular fingerprints allow differentiation based upon sequences of these highly conserved genes, antigenic and biological properties are generally consistent (Dumler et al. 1995b, 2001; Wen et al. 1995a, 1995b, 1996). *E. risticii* isolates differing in pathogenicity have been distinguished by restriction fragment length polymorphism (RFLP) analysis of genomic DNA probed with specific antigen gene probes or a partial *rrs* (16S rRNA gene) polymerase chain reaction (PCR) products (Chaichanasiriwithaya et al. 1994; Vemulapalli et al. 1995). Sequences of the *rrs* (16S rRNA gene) and *rrl* (23S rRNA gene) and the bacterial cell division gene *ftsZ* have provided evidence of multiple clades or lineages of *Wolbachia*-like symbionts and bacteria in a wide diversity of invertebrate species as well as helminths (Werren et al. 1995; Bandi et al. 1998; Lo et al. 2002). This monophyletic grouping contains up to six distinct internal clades, several of which are specifically associated with insects such as fruit flies, beetles, and mosquitoes, or with nematode helminths such as *Brugia*, *Onchocerca*, and *Dirofilaria*. Lineages of the *Wolbachia* spp. are exceptionally closely associated with their hosts suggesting long-term coevolution. The rRNA operons of *W. pipientis* are unusual in that *rrs* (16S rRNA) is unlinked to *rrl/rrf* (23S-5S rRNA) operon, and neither is it linked to tRNA-encoding sequences, each is present in a single genomic copy, and the antitermination boxes usually present in eubacteria are absent (Bensaadi-Merchermek et al. 1995). *Wolbachia* isolates from *Culex* and *Ephestia* differed in sequences flanking the rRNA operons although their rRNA operon sequences and organization were conserved. It is anticipated that a wealth of data regarding the overall genomic structure and biological capabilities will become available when genome sequences for several *Ehrlichia* spp (*E. chaffeensis*, *E. ruminantium*), *Anaplasma* spp. (*A. marginale*, *A. phagocytophilum*), *Wolbachia* spp., and *Neorickettsia sennetsu* are released.

An increasing number of genes of *Anaplasmataceae* have been cloned and evaluated as part of analyses of immunological reactions and as antigens for serodiagnostic tests. For *Neorickettsia*, these include the 44-, 51-, 55-, 70-, and 85-kDa antigen genes of *N. risticii* (Dutta et al. 1991; Vemulapalli et al. 1995) and the *groEL* of *N. risticii* and *N. sennetsu*, as well as the *gltA* (citrate synthase) or *N. risticii*. Many more genes have been cloned and analyzed for the *Ehrlichia* genus, including *rrs* (16S rRNA), the *groE* operons, *gltA*, 120- and 140-kDa antigen genes of *E. chaffeensis* and *E. canis*, and multigene families that are regular components of the genomes of *Ehrlichia*, *Anaplasma*, and *Wolbachia* spp. (Sumner et al. 1993; Yu and Walker 1995; Ijdo et al. 1998; Jiggins et al. 2002). Initially identified by the immunodominance of these protein antigens

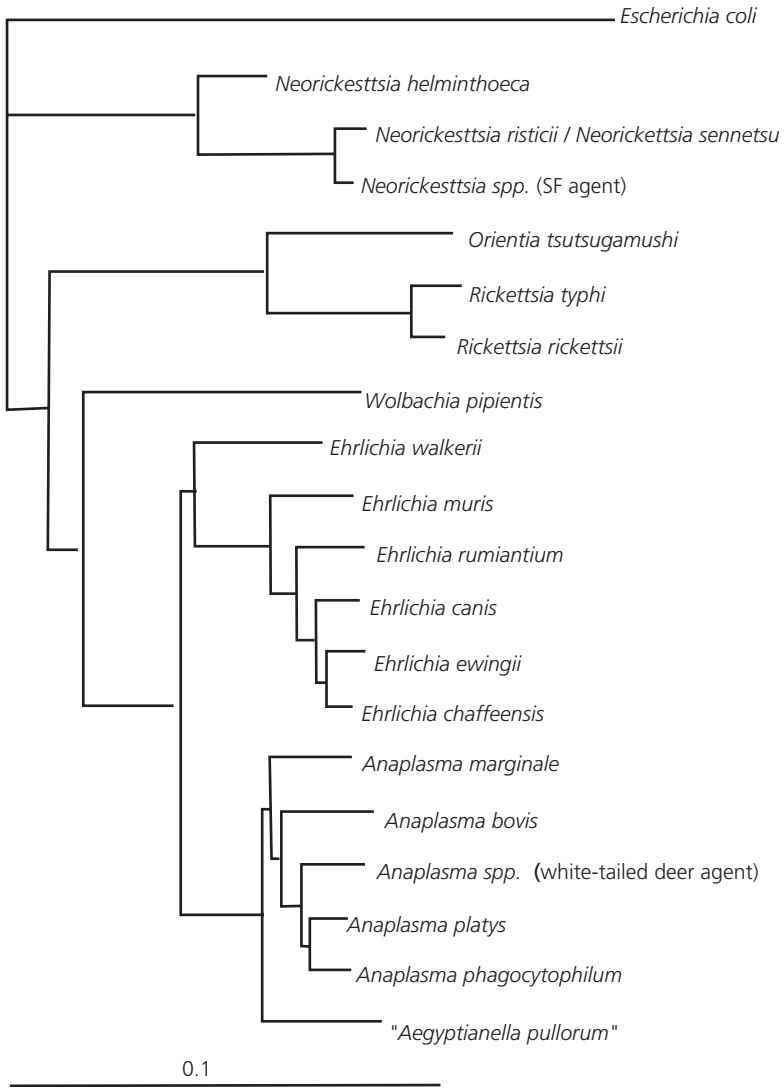

Figure 2 *Phylogenetic relationships among current members of the family* Anaplasmataceae. *The tree was generated by clustal alignment of* rrs *(16S rRNA gene) sequences from the organisms shown using the neighbor-joining method. The bar indicates the number of substitutions per 1000 bp.*

using polyclonal sera and later using monoclonal antibodies, the antigens encoded by these genes have a conserved domain referred to in the National Center for Biotechnology Information's (NCBI) Conserved Domain Database (www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml) as 'pfam01617.8, Surface_Ag_2;' other proteins that contain this domain include the phase-variable integral membrane opacity (Opa) porin proteins of pathogenic *Neisseria* spp. that also mediate pathogen-host–cell interactions. The domain architecture has been detected in protein families denoted as major surface protein-2 (MSP-2) in *Anaplasma marginale*, *Anaplasma ovis*, and *Anaplasma centrale*, as major surface protein-4 (MSP-4) in *Anaplasma marginale*, as major surface protein-2 (Msp2), P44, HGE-44, and '44-kDa antigen' in *Anaplasma phagocytophilum*, as P28 or Omp-1 in *Ehrlichia chaffeensis*, *Ehrlichia canis*, *Ehrlichia muris*, and *Ehrlichia ewingii*, as MAP1 and MAP2 in *Ehrlichia ruminantium*, and as outer-membrane protein precursors or *Wolbachia* surface proteins (Wsp) in *Wolbachia* spp. pfam01617.8, Surface_Ag_2 sequences have not yet been detected in *Neorickettsia*. The prevailing pattern of the pfam01617.8, Surface_Ag_2-related gene families is the presence of multiple paralogs within the genome, and the gene structure is characterized by conserved regions that flank hypervariable sequences. In *E. chaffeensis* and *E. canis*, the *p28* paralogs are tandemly arranged in a single genomic cluster and each possesses unique promoters that could allow the genes to become transcribed independently in vitro and possibly in vivo. In *Anaplasma marginale*, and probably in *A. phagocytophilum*, the paralogs are distributed through the genome in small clusters of three to six paralogs that lack individual promoters. It is now believed that a single or small number of promoter sites are present in the *Anaplasma* genome, and that expression of individual paralogs may

require gene conversion. An in-depth analysis of the structure of the pfam01617.8, Surface_Ag_2 paralogs of *Ehrlichia* and *Anaplasma* indicates the presence of additional conserved sites that may allow both gene conversion and intragenic recombination, and that successive combinatorial changes could yield enormous genetic and antigenic diversity. The underlying potential genetic heterogeneity is not limited to intact paralogs, even if combinatorial processes allow frequent recombination among these 'pseudogenes.' An analysis of the nearly complete *A. phagocytophilum* genome for Msp2-like sequences in contiguous open reading frames of at least 100 amino acids identified at least 52 paralogs – an enormous genetic reservoir that may in part explain the success of these bacteria despite highly restrictive niches (Scorpio et al. 2004).

The major function of the pfam01617.8, Surface_Ag_2 family is not known, but roles in antigenic diversity and as adhesins are suggested by extrapolation from *Neisseria*. In fact, antigenic diversity is a well-established principle for survival of *A. marginale* infection of cattle, and increasing evidence suggests that similar genetic changes that promote antigenic diversity may play a role in immune evasion for *Ehrlichia chaffeensis*, *Ehrlichia canis*, and *A. phagocytophilum*. The preferential expression of some paralog-encoded antigens in mammalian cells in vitro, or with in vivo mammalian or tick infections, suggests other potential roles. MSP2 of *A. marginale* forms membrane complexes with at least four other surface-exposed proteins, and limited evidence suggests that adhesion to erythrocytes occurs via this complex. Similarly, Msp2 of *A. phagocytophilum* in part mediates adhesion of the bacterium to granulocyte surfaces, in particular platelet selectin glycoprotein ligand-1 (PSGL-1), proving a role for this protein as an adhesin. Given the degree of relationship among the pfam01617.8, Surface_Ag_2-like sequences, it is not surprising that variable degrees of antigenic cross-reactivity are detected, more among phylogenetically close *Anaplasmataceae*; in fact, the tremendous potential for heterogeneity of surface antigens suggests that at least some of the serological cross-reactivity may be due to the expression of other antigenically similar proteins.

Other genes of potential importance have been identified and cloned. *Ehrlichia chaffeensis* and *E. canis* possess genes that encode immunodominant 120- and 140-kDa glycoprotein antigens, respectively, that may also be adhesins (McBride et al. 2000; Popov et al. 2000), and similar sequences are identified in the genes that encode 100-kDa (*gra*) and 130-kDa (*rea*) antigens of *A. phagocytophilum* (Storey et al. 1998). Another shared genomic characteristic is the presence of eight genes (four each of *virB* and *virD*) that encode the machinery for type IV secretion and that are clustered in two separate loci in the genomes of both *E. chaffeensis* and *A. phagocytophilum* (Ohashi et al. 2002). The genes encoding these putative virulence factors are colocalized and polycistronically transcribed with *sodB* and an *msp2* paralog. As the superoxide dismutase product of *sodB* possesses a metal ion cofactor, metal-rich environments probably regulate the gene, such as in proximity to or within a eukaryotic vacuole. The resulting transcription of *msp2* may permit enhanced expression of this adhesin. A similar genomic arrangement has been described for *Wolbachia* spp., although transcriptional analysis has yet to be conducted (Masui et al. 2000). *A. phagocytophilum ankA* encodes a 160-kDa protein antigen called AnkA that has at least 11 tandemly repeated ankyrin motifs and that translocates into the nucleus of the infected neutrophil and complexes with host-cell chromatin (Storey et al. 1998; Caturegli et al. 2000). The function of this protein is not known, but it is reasonably conserved regardless of geographic origin.

CELL-WALL COMPOSITION AND ANTIGENIC PROPERTIES

Ultrastructural studies indicate that the cell wall of *Anaplasmataceae* is similar to that of other gram-negative bacteria, but no obvious peptidoglycan layer is visible. Although biological responses characteristic of exposure to LPS have been demonstrated for *Wolbachia* spp. (Taylor et al. 2000), genes encoding biomachinery are absent from the genomes of *E. chaffeensis*, *A. phagocytophilum*, and *W. pipientis* (Lin and Rikihisa 2003; Wu et al. 2004). Techniques that examine the components of the cell wall have shown the presence of a number of integral membrane proteins, the most abundant of which are the pfam01617.8, Surface_Ag_2 proteins, although numerous other proteins can be visualized. A total of 18 *N. risticii* proteins were identified by surface iodination and radioimmunoprecipitation, nine of which were prominent when examined using homologous polyclonal sera. Antisera from different species, as well as from individual animals, exhibited differences in reactivity to *E. risticii* antigens. *N. risticii* and *N. sennetsu* share many antigens, including those of 110, 70, 58, and 44 kDa (Dasch et al. 1990; Shankarappa et al. 1992), but in accordance with phylogenetic placements, most react with *N. helminthoeca* and only a few react with *E. canis* (Rikihisa 1991b; Shankarappa et al., 1992). In fact, *N. sennetsu* immunization protects ponies against challenge with *N. risticii* and elicits strong serologic reactivity to the shared 44-kDa protein. However, mice that were protected against *N. risticii* challenge by a killed homologous vaccine reacted primarily to 33-, 57-, and 100-kDa antigens (Rikihisa 1991c).

In the genus *Ehrlichia*, a number of antigens can be detected in whole-cell immunoblot preparations. *E. chaffeensis* has 20 protein antigens detectable with homologous antisera. Cross-reactions occur most strongly with antisera to other *Ehrlichia* spp., including *E. canis*, *E. ewingii*, *E. ruminantium*, and *E. muris*.

Based upon immunofluorescence reactions using whole cells rather than defined proteins, serologic reactions among *Ehrlichia* spp. can not be easily distinguished, even with differential titers. Western blot analyses reveal a broad range of serologically cross-reactive proteins, including some shared broadly among bacteria outside of the *Ehrlichia* genus (e.g. GroESL heat-shock proteins), some apparently unique to the genus, and even some that weakly react with antigens expected to be unique for the species (Unver et al. 1999; Bowie et al. 1999). Study of the antigenic specificity of the pfam01617.8, Surface_Ag_2 proteins for individual *Ehrlichia* spp. has revealed contradictory results, although serologic cross-reactions are not often detected. However, the phylogenetic relationships among members of the genus and the high degree of pair-wise nucleotide and predicted amino-acid similarity in the pfam01617.8, Surface_Ag_2 gene and protein conserved regions suggests a low but real likelihood of shared or common epitopes. For *Ehrlichia*, the only known potential adhesin is the gp120 of *E. chaffeensis*, which is also the only protein expressed to a higher degree on dense core cells (Yu et al. 2000; Popov et al. 2000).

Anaplasma marginale is the best antigenically characterized species of the genus. It has six distinct major surface proteins (MSP1a, MSP1b, MSP-2, MSP-3, MSP-4, and MSP-5) associated with the three potential adhesins, MSP1a, MSP1b, and MSP2 (Vidotto et al. 1994; McGarey and Allred 1994a; McGarey et al. 1994b). These proteins interact in the membrane and can be co-immunoprecipitated after treatment with cross-linking reagents. Under nonreducing conditions, MSP2 and MSP5 form disulfide-linked multimers (Vidotto et al. 1994). MSP2 migrates as multiple spots on two-dimensional gels (Zakimi et al. 1994). MSP1 complexes consist of a heterodimer of both disulfide and noncovalently associated MSP1a and 1b polypeptides. *A. marginale* bind to erythrocytes and tick cells in vitro via MSP1, and MSP1 antibody inhibits tick-cell infectivity consistent with earlier observations suggesting a direct role as an adhesin (de la Fuente et al. 2001; McGarey and Allred 1994a; Blouin et al. 2003). *A. phagocytophilum* also possesses a large number of antigens visualized in immunoblots. The most quantitatively and immunologically dominant protein is Msp2, which varies in size from 40 to 50 kDa and in structure on strains from different geographical regions. Msp2 expression also changes over generations owing to gene conversion and recombination of Msp2 gene sequences or modifications in *msp2* mRNA (Caspersen et al. 2002; Barbet et al. 2003). Park et al. (2003) described the role of *A. phagocytophilum* Msp2 as an adhesin for binding to neutrophils, suggesting the importance of a complex of major surface proteins for binding by *Anaplasma* spp. AnkA is a 155–160-kDa protein (Storey et al. 1998; Massung et al. 2000) that is secreted from *A. phagocytophilum* and eventually gains access to the host cell nucleus where it binds to the chromatin (Caturegli et al. 2000). AnkA antigens are not detected in *Ehrlichia* spp. As for *Ehrlichia* and *Neorickettsia*, *Anaplasma* also possess antigenic GroESL that cross-reacts widely with other *Anaplasmataceae* and many other unrelated bacteria.

Frequent serologic reactions between *A. phagocytophilum* and *Ehrlichia* spp. are detected, largely owing to reactions between heat-shock proteins that share similar epitopes, but potentially to a lesser degree by virtue of epitopes shared on pfam01617.8, Surface_Ag_2 proteins (Wong et al. 1997; Unver et al. 2001a). In fact, the prior taxonomic classification scheme was based in part upon degrees of serologic cross-reactivity, and despite unique taxonomic positions and the lack of shared pfam01617.8, Surface_Ag_2 proteins, serologic cross-reactivity between *Ehrlichia*, *Anaplasma*, and *Neorickettsia* spp. has been demonstrated (Chen et al. 1994b; Rikihisa et al. 1994; Wen et al. 1995a; Dumler et al. 1995a). Regardless, most notable specific reactions appear directed toward the pfam01617.8, Surface_Ag_2 proteins, including: (i) P28 in *E. canis*, *E. chaffeensis*, *E. ewingii*, *E. muris*, and *E. ruminantium* (MAP1); (ii) Wsp (28 kDa) in *Wolbachia* spp.; and (iii) Msp2 (40–50 kDa) in *Anaplasma marginale* and *A. phagocytophilum*. Although no pfam01617.8, Surface_Ag_2 protein homolog has yet been identified in *Neorickettsia*, this genus demonstrates the presence of dominant 80-, 70-, and 64-kDa protein antigens, of which the latter probably represents GroESL (Rikihisa 1991b). Other surface antigenic proteins of importance include a low-molecular-weight protein (approximately 20 kDa) called MSP5 in *A. marginale* and *A. centrale*, and MAP2 in *E. canis*, *E. chaffeensis*, and *E. ruminantium*. These proteins possess a conserved domain shared by SCO1/SenC/PrrC proteins that are involved in involved in biogenesis of respiratory and photosynthetic systems of α-proteobacteria, *Rickettsia conorii*, and *Rickettsia prowazekii* and also in mitochondria. The function in *Anaplasmataceae* is not known.

Considerable study has been made regarding the protective nature of immune reactions toward antigens of the *Anaplasmataceae*. Most study has been directed at veterinary control of heartwater (*E. ruminantium*) and anaplasmosis (*A. marginale*). The consensus of opinion now favors an important role for the generation of activated macrophages through the action of interferon-γ (IFNγ) that either acts directly on infected cells or facilitates destruction of antibody opsonized bacteria during the extracellular transition (Palmer et al. 1999; Akkoyunlu and Fikrig 2000; Banerjee et al. 2000; Van Kleef et al. 2002). Other observations focus upon specific antigens that induce antibody and immune responses that protect against virulent challenge. These studies implicate series of major surface antigens, usually of low molecular size (13–18 kDa and the 31-kDa MAP1) for *E. ruminantium* (Van Kleef et al. 2002)

and usually directed against the MSP1 complex (MSP1α and MSP1β) for *A. marginale* (Brown et al. 2001). Of interest is the observation that passive antibody administration abrogates *E. chaffeensis* and *A. phagocytophilum* infection in mice (Winslow et al. 2000; Sun et al. 1997). Moreover, the use of monoclonal antibodies as passive immunization to *E. chaffeensis* pfam01617.8, Surface_Ag_2 protein P28 provides protection whereas those to *A. phagocytophilum* pfam01617.8, Surface_Ag_2 protein Msp2s are only variably protective (Li et al. 2001; Kim and Rikihisa 1998). Mouse models also illustrate the important role of IFNγ in clearance of bacteria in both *E. chaffeensis* and *A. phagocytophilum*, although emerging data support a direct role for the immune response in the development of histopathologic lesions, clinical signs, and disease (Akkoyunlu and Fikrig 2000; Martin et al. 2000, 2001).

IDENTIFICATION AND TYPING METHODS

Morphologic methods are not specific enough alone to differentiate among *Ehrlichia*, *Anaplasma*, or *Neorickettsia* spp. The infected host and infected cell provide abundant information but rarely provide sufficiently specific information for a definitive identification. For example, *A. marginale* and *A. centrale* are located as clusters of bacteria in bovine erythrocytes, *Ehrlichia chaffeensis* and *N. sennetsu* are identified as bacterial clusters in human peripheral blood monocytes, *Anaplasma phagocytophilum* and *Ehrlichia ewingii* are identified in human or other mammalian neutrophils, *Ehrlichia ruminantium* may be observed as clusters in bovine endothelial cells, while *A. platys* and rarely other *Ehrlichia* and *Anaplasma* spp. are found in platelets. *Wolbachia* spp. have only been visualized in arthropod and nematode tissues. However, the abundance of newly identified species in *Anaplasmataceae*, and the overlapping hosts and host cell range, have reduced this simple morphological scheme for differentiation to a screening tool only.

Originally, identification of the various members of *Anaplasmataceae* in clinical or tick samples was based primarily on indirect fluorescent antibody reactivity with specific sera. Recently, molecular methods and DNA sequencing have supplanted these less specific identification tools (Dumler et al. 2001; Inokuma et al. 2002). PCR primers specific for nearly every member of the *Ehrlichia*, *Anaplasma*, and *Neorickettsia* spp. have been developed and described, including the conserved targets *rrs* (16S rRNA gene), *groESL* operon, *gltA* (citrate synthase), and a variety of antigen-encoding genes, especially those that encode pfam01617.8, Surface_Ag_2 proteins (Anderson et al. 1991; Massung and Slater 2003; Olano and Walker 2002; Inokuma et al. 2002; Cheng et al. 2003). Each target has advantages and disadvantages: genes involved in housekeeping function and RNA transcription are generally present as single copies or in low copy numbers, whereas several multigene families possess species-specific sequences that are present in multiple copies in the genome, facilitating sensitive identification. As the level of genetic similarity among many species is high, it is advantageous to confirm the identity of a specific molecular identification by sequence analysis.

Serologic tests generally identify *Anaplasmataceae* within the genus; however, cross-reactions out of the genus, especially between *Anaplasma* and *Ehrlichia* spp., are frequent. Thus, protein immunoblotting has been particularly useful in demonstrating antigen variation and differences between genera, between species, and even among strains within species. For example, *N. risticii* strains that vary in pathogenicity may be partly differentiated by a panel of monoclonal antibodies that identifies unique epitopes on the 51- and 85-kDa proteins (Chaichanasiriwithaya et al. 1994; Vemulapalli et al. 1995). Reactivity of sera with pfam01617.8, Surface_Ag_2 protein antigens of *E. chaffeensis*, *E. canis*, and *E. ruminantium* (P28 or MAP1) or with *A. phagocytophilum* (Msp2 or P44) has been suggested as a specific means to distinguish between infections by these organisms (Dumler and Bakken 1995). However, the use of cloned recombinant proteins for detection of serological responses has been confusing and disappointing probably owing to the high degree of genetic and antigenic diversity of immunodominant targets such as pfam01617.8, Surface_Ag_2 protein antigens. Moreover, no specific means exist for differentiation of strains with varying degrees of virulence, although recent evidence suggests that some genetic markers may allow differentiation of *A. phagocytophilum* strains pathogenic for humans (Massung et al. 2000; Petrovec et al. 2002). (Table 2).

TRANSMISSION, PATHOGENESIS, AND CLINICAL MANIFESTATIONS

Ehrlichia genus human infections

Human infection by members of the genus *Ehrlichia* has been limited to *E. chaffeensis*, *E. ewingii*, and, in a single patient, *E. canis* (Olano and Walker 2002; Buller et al. 1999; Perez et al. 1996).

HUMAN MONOCYTIC (MONOCYTOTROPIC) EHRLICHIOSIS (*EHRLICHIA CHAFFEENSIS*)

The vast majority of cases have resulted from infection by *E. chaffeensis*, a bacterium that infects predominantly monocytes in the blood and mononuclear phagocytes in tissues and organs. Thus, this infection has been named human monocytic (or monocytotropic) ehrlichiosis (HME). Unfortunately, most diagnoses of *E. chaffeensis* infection are established based upon the detection of

Table 2 *Clinical manifestations of human infections by* Ehrlichia *and* Anaplasma

Disease	Human monocytic ehrlichiosis	Ehrlichiosis 'ewingii'	Human anaplasmosis (formerly human granulocytic ehrlichiosis)
Causative agent	*Ehrlichia chaffeensis*	*Ehrlichia ewingii*	*Anaplasma phagocytophilum*
Severity	Moderate to severe	Mild to moderate	Mild to severe
Fever, headache, myalgias	Yes	Yes	Yes
Rash	36–40%	0%	$\leqslant$10%
Type of rash	Maculopapular or petechial	None described	Maculopapular
Respiratory tract involvement	25%	0%	10–20%
CNS involvement	20%	0%	rare
Thrombocytopenia	72%	75%	78%
Leukopenia	60–74%	75%	53%
Case-fatality ratio (%)	2%	0%	<1%

CNS, central nervous system.

E. chaffeensis antibodies in convalescence, and it is now increasingly recognized that this serological approach is not highly specific for differentiation of HME from infections caused by *E. ewingii* or *A. phagocytophilum*. It is estimated that approximately 10 percent of some serologically diagnosed *E. chaffeensis* infections may actually result from *E. ewingii* (Buller et al. 1999), and it is equally well recognized that between 10 and 40 percent of sera that react with *E. chaffeensis* cross-react with *A. phagocytophilum* (Wong et al. 1997). Despite these caveats, increasing knowledge about the infection in humans is accumulating. HME is characterized as an 'influenza-like' infection, and most patients present with fever, headache, and myalgias (Olano and Walker 2002). Approximately half or less develop manifestations attributable to the gastrointestinal system (nausea, vomiting, diarrhea, abdominal pain), and cough or radiographic evidence of respiratory involvement is observed in about 25 percent. Of interest is the frequent (20 percent) development of central nervous system (CNS) manifestations, often confirmed by cerebrospinal fluid (CSF) pleocytosis. Skin rash is much less common than with vasculotropic rickettsioses, and is present as a macular, maculopapular, or petechial rash on the trunk or extremities in 30–40 percent of patients, but only in 6 percent at presentation. Children more frequently develop rash with HME, up to 100 percent in some series (Schutze and Jacobs 1997). Characteristic laboratory findings including the presence of leukopenia in 60–74 percent, thrombocytopenia in 72 percent, and mild to significant elevations in serum transaminase activities in up to 90 percent of infections. Both leukopenia and thrombocytopenia are most often mild to moderate, but profound reductions ($<1 \times 10^9$ white blood cells (WBC)/L or $<10 \times 10^9$ platelets/L) are sometimes observed. An interesting set of hematological abnormalities may occasionally occur, including very early neutropenia and lymphopenia, followed by a left shift despite the leukopenia. After about 1 week, a reactive atypical lymphocytosis may be present; the atypical lymphocytes are phenotypically γδT cells (Caldwell et al. 1995). Although nonspecific, anemia is also often detected. Despite the frequent (90 percent of patients) mild to moderate elevations in serum aminotransferase levels, hepatic function is usually not impaired (Smith-Sehdev and Dumler 2002). Rarely, marked elevations occur, suggesting the possibility of viral hepatitis. In addition, increases in serum alkaline phosphatase occur in 25–60 percent and may suggest cholestasis (Nutt and Raufman 1999).

HME is a relatively severe infection that results in approximately 60 percent of patients requiring hospitalization, and an average of 3 weeks before return to normal activities. The case fatality rate is between 2 and 3 percent, and severe complications include meningoencephalitis, acute respiratory distress, hepatitis and hepatic failure, toxic or septic shock-like condition, renal failure, cardiomyopathy, coagulopathy and hemorrhage, fulminant infection in immunocompromised patients (HIV, organ transplantation, corticosteroid therapy), and the development of opportunistic infections by fungi and viruses.

Pathological samples from patients with HME demonstrate no vasculitis but have evidence of diffuse tissue mononuclear phagocyte activation with occasional granuloma formation and mononuclear phagocyte infiltrates in tissues (Walker and Dumler 1997; Dumler et al. 1993; Marty et al. 1995; Smith-Sehdev and Dumler 2002). Scattered perivascular lymphohistiocytic infiltrates in liver, lung, brain, and other tissues are evidence of disseminated low-level inflammation. Normocellular and hypercellular bone marrows are typical, favoring the concept of leukopenia and thrombocytopenia caused by peripheral sequestration or consumption rather than bone-marrow suppression (Dumler et al. 1993); similarly, the level of bacteremia is insufficient to explain leukocyte destruction, especially given the pancytopenia of multiple hematopoietic lineages that are not suscep-

tible to *E. chaffeensis* infection. Focal hepatocyte necroses with or without adjacent inflammatory foci may explain elevations in serum hepatic transaminases. *E. chaffeensis* are only infrequently observed in tissue samples, except when obtained from immunocompromised individuals who often develop fulminant infection (Paddock et al. 1993; Marty et al. 1995; Smith-Sehdev and Dumler 2002). In some patients, significant liver injury with focal hepatocellular necrosis and cholangitis with cholestasis are observed (Smith-Sehdev and Dumler 2002). The discrepancy between the quantity of bacteria in the tissues and the degree of pathologic injury suggests that the pathogen triggers an immunopathologic response rather than directly causing tissue injury. Thus, the current working hypothesis about pathogenesis with *E. chaffeensis* is that infection perturbs mononuclear phagocyte function, important regulators of proinflammatory response, thus allowing inflammation to proceed out of proportion to the level of infection. Both humoral and cellular immunity are likely to participate in recovery and eradication of infection, but macrophage activation by IFNγ is probably pivotal (Winslow et al. 2000; Barnewall and Rikihisa 1994). In fact, *E. chaffeensis* infection in the absence of opsonizing antibody suppresses cytokine production by macrophages and promotes a moderate anti-inflammatory response by production of interleukin-10 (IL-10) (Lee and Rikihisa 1996). Dichotomously, macrophage infection in the absence of immune response also promotes penetration of infected cells through endothelial cells, fixing subsequent proinflammatory responses into target tissues and organs (Park et al. 2003). Internalization of *E. chaffeensis* opsonized by antibody leads to a marked proinflammatory response heralded by production of TNFα, IL-1β, and IL-8 (Lee and Rikihisa 1997).

'EHRLICHIOSIS *EWINGII*' (*EHRLICHIA EWINGII*)

During routine application of PCR diagnostics for HME in an endemic region, it was discovered that approximately 10 percent of patients with *Anaplasmataceae* DNA in blood were not infected with *E. chaffeensis*, and sequence analysis revealed human infection by *Ehrlichia ewingii*, only previously known as a pathogen of canine neutrophils. To avoid increasing confusion of disease names, some have elected to call this condition 'ehrlichiosis ewingii.' Three of the first four patients were immunocompromised and infection of peripheral blood neutrophils was detected in two of these patients. Since that time, *E. ewingii* has been implicated in a limited number of human infections, in both immune-competent and immune-suppressed individuals (chiefly HIV-infected). As *E. ewingii* and *E. chaffeensis* are close phylogenetic relatives, there is considerable serologic cross-reactivity; thus, serologic testing based upon whole cell methods is unable to distinguish *E. ewingii* from *E. chaffeensis* infections. However, in seropositive convalescent sera tested in protein immunoblots, the absence of reactivity with the P28 of *E. chaffeensis* and *E. canis* suggests *E. ewingii* infection. Overall, clinical manifestations are similar to those observed with *E. chaffeensis*, and are dominated by fever, with fewer patients having headache, myalgias, and malaise. Leukopenia, thrombocytopenia, and elevated serum hepatic transaminase levels are also observed. The infection appears to be less severe than for *E. chaffeensis*, but too few cases have been identified and described to make any certain conclusions. Pathological investigations of humans with *E. ewingii* infection have not been reported.

Persistent, asymptomatic *Ehrlichia canis* infection in a human

An *E. canis* strain was isolated from a seropositive, asymptomatic human in Venezuela (Perez et al. 1996). The patient was seropositive for at least 1 year, and no antibiotic therapy was given before blood was obtained for culture. It is reported that morulae were observed in leukocytes in the peripheral blood, and the patient's laboratory examination was unremarkable with the exception of a relative (50 percent) lymphocytosis. The identity of the isolate was confirmed by comparison with an *E. canis* isolate obtained from seropositive Venezuelan dogs (Unver et al. 2001b).

Anaplasma genus human infections

HUMAN ANAPLASMOSIS (FORMERLY GRANULOCYTIC EHRLICHIOSIS) (*ANAPLASMA PHAGOCYTOPHILUM*)

Human infection by members of the genus *Anaplasma* has so far been limited to only *Anaplasma phagocytophilum*. Unlike *E. chaffeensis*, but similar to *E. ewingii*, *A. phagocytophilum* infects predominantly cells derived from bone marrow myeloid cells, chiefly neutrophils in the blood and perhaps immature myelomonocytic precursors in the bone marrow (Bakken et al. 1994; Bakken and Dumler 2000). Initially, infection of humans was recognized as caused by an 'ehrlichia,' and because of the neutrophil host cells, the disease was called human granulocytic ehrlichiosis (HGE). More than 10 years have passed since the distinction of *A. phagocytophilum* infections from those caused by *E. chaffeensis* in humans; however, many diagnoses are still miscategorized as a result of incomplete diagnostic evaluation based upon flawed serological principles and studies that do not differentiate the serologically cross-reactive species. The situation is even more complex for *A. phagocytophilum* infections because of nomenclature difficulties. For several years, the specific identity of the bacterial cause of HGE was unclear. In 2001, the taxonomy of the HGE agent and closely related species

assigned to the genus *Ehrlichia* was revised to reflect a more accurate genetic phylogeny in the genus *Anaplasma*, where the HGE agent, *Ehrlichia equi*, and *Ehrlichia phagocytophila* were unified under the single species name, *A. phagocytophilum*. Although the name is more accurate, the accomplishments of Stannard, Gribble, and Madigan, who investigated *E. equi*, should not be forgotten (Stannard et al. 1969; Madigan and Gribble 1987). Moreover, the new taxonomic position creates a discrepancy in the disease name that formerly reflected the genus *Ehrlichia*. A more rational and increasingly accepted designation for HGE is human anaplasmosis, as it will be called here.

Human anaplasmosis, as for related infections, is characterized as 'influenza-like,' with a clinical presentation dominated by fever, and, less often, rigors; approximately 65–85 percent have headache, and myalgias are frequent. Gastrointestinal system involvement with nausea, vomiting, diarrhea, or abdominal pain is present in about one-third to one-half of patients, and cough or radiographic evidence of respiratory involvement is observed in about 30 percent (Bakken and Dumler 2000; Aguero-Rosenfeld et al. 1996). About 17 percent also present with some degree of confusion, but objective evidence of CNS infection with CSF pleocytosis is very rare (Bakken and Dumler 2000; Lee et al. 2000). Skin rash is seen also very infrequently, not more often than 10 percent of patients, and in many of these the skin is involved as erythema migrans because of cotransmitted *Borrelia burgdorferi* (Aguero-Rosenfeld et al. 1996). Laboratory findings include leukopenia in 53 percent, thrombocytopenia in 78 percent, and mild to significant elevations in serum transaminase activities in up to 90 percent of infections (Bakken et al. 2001). A majority of patients have either a normal leukocyte or platelet count at presentation, and their nadirs occur after about 5 and 7 days, respectively. During the first week, many patients will also have a left shift, giving the impression of a relative neutrophilia if a careful evaluation is not conducted (Bakken et al. 2001). During the second week, a reactive lymphocytosis may be present as also seen in HME. Despite the frequent (90 percent of patients) mild to moderate elevations in serum aminotransferase levels, hepatic function is usually not impaired. The C-reactive protein is often elevated with anaplasmosis and may assist in differentiation from viral infections (Bakken et al. 1996; Lotric-Furlan et al. 2000).

Human anaplasmosis varies in severity from mild, possibly subclinical, to severe and fatal (Olano and Walker 2002; Bakken and Dumler 2000; Blanco and Oteo 2002). For reasons that have yet to be defined, infections in the upper midwest USA are more severe than in the eastern USA, and these are more severe than observed in Europe. In the USA, more than half of patients require hospitalization, and up to 17 percent are admitted for care into an intensive care unit. The average interval of hospitalization is 6 days. The case fatality rate is <1 percent, but severe complications include opportunistic fungal and viral infections, severe nosocomial infections, acute respiratory distress, toxic or septic shock-like condition, renal failure, rhabdomyolysis, myocarditis, neuropathies, coagulopathy, and hemorrhage. Because *A. phagocytophilum* is transmitted by the bites of *Ixodes* spp. ticks that also harbor a variety of human pathogens, coinfections with such agents as *B. burgdorferi* or *Babesia microti* have been reported (Krause et al. 2002; Moss and Dumler 2003; Nadelman et al. 1997). The concept of enhanced clinical severity of these infections during human anaplasmosis is unproven, although animal models have provided compelling data suggesting this possibility. In theory, European patients in tick-borne encephalitis (TBE) endemic regions could be at risk for concurrent TBE and anaplasmosis (Lotric-Furlan et al. 2000).

Little histopathologic examination has been conducted in tissues from patients with anaplasmosis. Most examinations are performed in post-mortem examinations and are confounded by pathology resulting from opportunistic or nosocomial infections. However, sufficient examination has been conducted to determine that the overall histopathologic changes are similar to those observed with natural and experimental equine and canine infections and are also similar to changes observed with infection by *E. chaffeensis* (Walker and Dumler 1997; Lepidi et al. 2000). The major findings are in mononuclear phagocyte organs, where histopathologic evidence of macrophage activation is present. Such findings include mixed infiltrates with mononuclear phagocytes and lymphocytes, especially in the liver, where small nodular lymphohistiocytic lesions in hepatic lobules may be observed. On occasion, these nodules may also contain a single or several apoptotic cells, presumably hepatocytes, and a few neutrophils. The vast majority of these lesions lack any infected cells (Lepidi et al. 2000). The spleen often has an increase in foamy-appearing macrophages containing phagocytosed material, including erythrocytes, leukocytes, and platelets. The spleen is the organ within which most infected cells can be detected, but these are infrequent and not associated with the hemophagocytic cells (Walker and Dumler 1997). On occasion, lymph nodes may demonstrate paracortical hyperplasia – evidence of a T-lymphocyte mediated immune response. Bone marrow has been examined in only a small number of cases and is usually normocellular (Lepidi et al. 2000). The most dramatic findings in post-mortem examinations is the identification of opportunistic infections, which include fungal (disseminated infection and necrotizing esophagitis caused by *C. albicans*, *C. neoformans* pneumonia, invasive pulmonary aspergillosis) and viral infections (herpes simplex virus necrotizing esophagitis) (Bakken et al. 1996). Two patients with infectious esophagitis exsanguinated from their esophageal ulcers. One patient developed myocarditis of undetermined etiology but

suggestive of a viral infection (Jahangir et al. 1999). Although a higher level of bacteremia is detected with human anaplasmosis than with HME, the quantity of bacteria is still insufficient to explain the leukopenia, thrombocytopenia, and anemia (Walker and Dumler 1997; Lepidi et al. 2000). These features are best explained by the presence of activated and hemophagocytic macrophages, in spite of the paucity of infected cells that are usually detected in tissues. As in HME, this discrepancy suggests an immunopathologic mechanism, and experimental infections in mice confirm this possibility (Martin et al. 2001). Similar to the *E. chaffeensis* pathogenesis working hypothesis, infection with *A. phagocytophilum* leads to dichotomous neutrophil responses. Infected neutrophils are in part activated so that chemokines, but not proinflammatory cytokines, are produced (Klein et al. 2000), and cells show evidence of degranulation and secretion of metalloproteases and other biologically active products (Choi et al. 2003). In contrast, infected neutrophils are unable to (i) bind to endothelial cells owing to a loss of surface selectins (Choi et al. 2003), (ii) transmigrate endothelial barriers to the same degree as infected cells (Park et al. 2003), and (iii) engage in phagocytosis and to generate antimicrobial killing to the same degree as uninfected cells (Woldehiwet 1987; Banerjee et al. 2000). Humans with *A. phagocytophilum* infection develop high blood levels of IFNγ, and peripheral blood mononuclear cells from infected people release proinflammatory cytokines on exposure to *A. phagocytophilum* antigens (Dumler et al. 2000; Kim and Rikihisa 2000). In experimental mouse infections, IFNγ is critical for reduction of *A. phagocytophilum* bacterial load (Akkoyunlu and Fikrig 2000) but is also the major contributor to tissue histopathology and presumably disease manifestations (Martin et al. 2001). Thus, infected cells recruit mononuclear phagocytes and lymphocytes to promote inflammatory responses, but are unable to participate in either control of infectious agents or in regulation of the inflammatory response. As neutrophils are key modulators of inflammatory mediators, this situation allows a poorly regulated proinflammatory response that could account for many of the clinical manifestations and sequelae of human anaplasmosis.

Neorickettsia genus human infections

The only recognized species of *Neorickettsia* to produce clinical disease in humans is *N. sennetsu*. The infection results in a mononucleosis-like illness called sennetsu fever in Japan (Misao and Kobayashi 1955). There is also evidence for *N. sennetsu* infection of humans in Malaysia, but only a very small number of cases have been adequately proven and described altogether. The worldwide distribution of *N. risticii*, a very closely related species, suggests that human infection may occur more broadly as well. Sennetsu fever is relatively mild and no fatalities have been recorded. The pathogenesis in humans is essentially unstudied, but murine models have provided some insight. Clinical manifestations in humans include fever, malaise, and anorexia with lymphadenopathy. The presence of these findings and increased concentrations of peripheral blood atypical lymphocytes lead to clinical confusion with infectious mononucleosis. *N. sennetsu* has been isolated from blood, bone marrow, and lymph nodes of patients (Misao and Kobayashi 1955). Hyuganetsu, which is reported to be caused by the SF (*Stellantschasmus falcatus*) agent *Neorickettsia* species, appears to be clinically indistinguishable from sennetsu fever (Fukuda 1958; Fukuda and Yamamoto 1981); the genetic similarity of the SF agent to *N. sennetsu* argues that this is likely to be correct. In animals infected with either *N. risticii* or *N. helminthoeca*, the clinical manifestations often include severe diarrhea, but this has not been reported with human infections.

Wolbachia-associated human disease

The notion that *Wolbachia* spp. may contribute to human disease derives from the frequent detection of these endosymbionts in the tissues of nematodes that are the cause of filariasis, including river blindness and elephantiasis. These processes are associated with severe inflammation that leads to obstructive and fibrotic manifestations. In fact, such inflammatory reactions are also associated with nematodal death, either spontaneously or with therapy. The recent recognition that much of the inflammatory response is driven by 'endotoxic' activities, including activities related to CD14 and toll-like receptor-4, which derive from the endosymbiont *Wolbachia* spp., suggests that antimicrobial therapy directed at reduction in nematode bacterial burdens would be beneficial (Taylor 2002; Hoerauf et al. 1999). Considerable effort will be required in the future to conduct definitive studies, but the reward, if the hypotheses are validated, is the prevention of millions of deaths each year.

EPIDEMIOLOGY AND NATURAL HISTORY

Ehrlichia chaffeensis and *Ehrlichia ewingii*

As of the end of 2002, the Centers for Disease Control (CDC) had reported 1417 cases of HME in the USA in *Morbidity and Mortality Weekly Reports* since reporting began in 1987. In spite of the relatively low incidence that is calculated based upon these passively collected figures, a retrospective analysis by the CDC has revealed average annual rates of 5.53 cases per million in Arkansas, with the highest incidence of disease in the

adjacent south midwestern states of Missouri and Oklahoma, but also including high rates in Illinois, Kentucky, Indiana, and Tennessee. As for Rocky Mountain spotted fever, the incidence of HME is also high in the southeastern and mid-Atlantic USA, including North Carolina, Virginia, Maryland, and New Jersey. It is likely that the low reported incidence of infection in adjacent states is the result of under-recognition and nonmandatory reporting by the USA. The average age of infected patients is approximately 45 years, and the gender ratio is 2M:1F. However, severe and even fatal infections have been described in children. Between 60 and 80 percent of patients recognize a tick bite prior to onset of symptoms.

The specific distribution of HME results from the association of several factors, including the widening distribution of the tick vector, *Amblyomma americanum*, and its major host, *Odocoileus virginianus*, the white-tailed deer (Childs and Paddock 2003). *A. americanum* is an aggressive host-seeking tick that will feed on many different hosts, including man. All three life stages of *A. americanum*, larvae, nymphs, and adults, can feed on white-tailed deer. The rapid expansion of white-tailed deer populations and geographic range, and the high seroprevalence of infection and evidence of persistent *E. chaffeensis* bacteremia in the absence of any clinical signs make these the most significant reservoir hosts (Ewing et al. 1995). However, the promiscuous feeding behavior of *A. americanum* ensures that many other species may become infected, including canids (domestic dogs, coyotes, wolves, foxes), raccoons, opossums, goats, and potentially *Peromyscus leucopus* (white-footed mice), widening the potential spectrum of reservoir hosts (Childs and Paddock 2003; Paddock and Childs 2003). A potential role for avian species that may serve as hosts for immature *A. americanum* stages needs more investigation. Several factors may account for the recent emergence of HME including the increasing abundance of ticks and white-tailed deer, and the increasing overlap of human and deer habitats in the USA. An important role for dogs must be considered as these animals may become persistently and subclinically infected and are known vehicles for the transport of infected ticks into the domestic environment. Currently, only limited data suggest that *E. chaffeensis* occurs outside of North America, where the only known competent vector (*A. americanum*) exists. However, increasing interest and investigation have yielded compelling data about the presence of *E. chaffeensis* or similar species in ticks or as human infections in Asia, Africa, South America, and Europe (Paddock and Childs 2003). The epidemiological and ecological conditions for *E. ewingii* infection are nearly identical to those of *E. chaffeensis* owing to the shared tick vector, *A. americanum* (Childs and Paddock 2003; Yabsley et al. 2002). A few studies have documented the presence of *E. ewingii* DNA in from 5 to 20 percent of white-tailed deer in the midwest and southeastern USA (Yabsley et al. 2002; Steiert and Gilfoy 2002).

Anaplasma phagocytophilum

As of the end of 2002, the CDC had reported 1 423 cases of human anaplasmosis in the USA since the infection was first recognized in 1990. As for the low incidence of HME based upon similar passive reporting, average annual rates as high as 15.9 and 8.8 cases per million population have been reported for Connecticut and Wisconsin, respectively (McQuiston et al. 1999). An evaluation of incidence based upon active case surveillance has revealed much higher incidence rates; for example, the average annual incidence of infection in Spooner County, Wisconsin, from 1991 through 1996 and around Lyme, Connecticut, in 1998 was 58 cases and 51 cases per 100 000 population, respectively (Bakken et al. 1996; Ijdo et al. 2000). The highest rates of incidence for human anaplasmosis are found in the northern USA, including the northeastern states of Connecticut, New York, Rhode Island, Massachusetts, New Jersey, and Pennsylvania, and in the upper midwest states of Wisconsin and Minnesota, although a small focus of infection has also been described in northern California (Foley et al. 1999; Fritz et al. 1997). Although tick-borne fever of ruminants and related *A. phagocytophilum* infections of horses and dogs have been known in Europe for many years, human infection appears to be mild and often subclinical (Blanco and Oteo 2002). Although ample evidence of human infection based upon serological analyses is present in Europe, and despite the frequent presence of *A. phagocytophilum* in *Ixodes ricinus* ticks that are known to bite and transmit disease agents to humans, only 15 cases of human anaplasmosis have been reported from Europe, and most were identified in Slovenia or Sweden (Blanco and Oteo 2002; Lotric-Furlan et al. 1998; Bjoersdorff et al. 2002). The reasons for the discrepant occurrence of human disease between North America and Europe are unclear, but genetic analyses indicate that differences in the bacteria between these locations may be a fruitful area for investigation (Petrovec et al. 2002; Caturegli et al. 2000; Massung et al. 2000). As for HME, the average age of human anaplasmosis patients is more than 40 years, with twice as many infections in men. Pediatric infections occur and may also be severe (Lepidi et al. 2000; Moss and Dumler 2003; Arnez et al. 2001). Tick bites are documented in about three-fourths of all diagnosed patients.

The distribution of *A. phagocytophilum* infections in humans parallels that of other major *Ixodes*-associated zoonoses such as Lyme disease, babesiosis, and TBE. The *Ixodes persulcatus* group of ticks is distributed widely around the world, and important vectors of human infection include *I. scapularis* in the eastern

USA, *I. pacificus* in the western USA, *I. ricinus* in Europe and western Asia, and *I. persulcatus* in Asia. These ticks characteristically feed on several hosts, with each life stage having a range of preferred hosts. Thus, a variety of potential reservoirs for *A. phagocytophilum* exist, including small mammals such as *P. leucopus* (white-footed mouse) in the eastern USA, *Neotoma fuscipes* (the dusky footed woodrat) in the western USA, *Apodemus* spp. voles in Europe, and a variety of cervids (white-tailed deer, Columbian black-tailed deer, roe deer, red deer) or ruminants (goats, sheep, cattle), and as diverse as bear, canids, and even birds. Currently the best evidence for an animal reservoir exists for small mammals such as mice and voles (Telford et al. 1996; Des Vignes and Fish 1997) and cervids (Belongia et al. 1997; Alberdi et al. 2000; Foley et al. 1998), both of which are frequently infected, sustain prolonged bacteremia, and develop no clinical signs (Stuen et al. 2001; Magnarelli et al. 1999). Owing to a worldwide rapid expansion in deer populations as well as expansions in tick populations that infest deer and small mammals, the emergence of anaplasmosis can be in part understood.

Neorickettsia sennetsu

Tick transmission of *N. sennetsu* was suspected for many years, owing to an erroneous assumption regarding a close relationship to tick-borne rickettsioses and ehrlichioses. However, soon after the identification of *N. sennetsu* in humans, some epidemiological data suggested an association with consumption of red mullet fish. Although unproven for *N. sennetsu*, the related *N. helminthoeca* and the very similar *N. risticii* are both transmitted to mammalian hosts through the consumption of trematode-contaminated materials, such as raw fish, fresh-water snails, or insects with an aquatic stage that harbor *Neorickettsia*-infected trematode cercariae.

SPECIMEN COLLECTION AND DIAGNOSIS

Because of the nonspecific clinical manifestations of human *Ehrlichia* and *Anaplasma* infections, laboratory testing is needed to confirm an etiologic diagnosis. Many techniques have been developed and evaluated, but serological testing remains the most simple and effective approach to diagnosis. Cultivation techniques have improved but are largely limited to major reference and public health laboratories. Unfortunately, serologic methods generally require a comparison of acute and convalescent sera, and culture often requires a week to more than a month before results are obtained. Molecular techniques are becoming increasingly used and are important to establish an early diagnosis at a time when therapeutic decisions are being made. However, neither serology nor isolation allows a diagnosis to be made early enough to affect patient management.

Rapid methods that may suggest a diagnosis should be attempted, such as simple microscopic examination of a Romanowsky-stained blood film. Morulae can be detected in peripheral blood leukocytes of patients with HME or anaplasmosis, but this technique is extremely laborious and is only about 2 percent sensitive for HME and between 25 and 75 percent sensitive for human anaplasmosis (Dumler and Bakken 1995). Many laboratories now offer direct PCR amplification of *E. chaffeensis* or *A. phagocytophilum* nucleic acids from the acute-phase blood of suspected patients. This approach does not identify the closely related *E. ewingii*. Thus, some laboratories have devised 'universal' amplification methods that target regions specific for *Anaplasmataceae* on highly conserved genes, and follow a positive test with a second specific PCR or with sequence analysis of the amplicon from the universal method. Each has advantages and disadvantages: the universal approaches are generally less sensitive than specific amplifications, but can detect a broader range of microbes; a direct amplification approach allows a more rapid identification rather than the universal approach, which requires a second stage of analysis. A significant potential advantage of the universal approach is the ability to recognize new infectious agents that may be related to the species of interest. Sensitivity and specificity of the diagnostic molecular reactions may differ considerably depending upon the target gene selected, the method of DNA preparation, and the quality and integrity of the sample to be tested.

Serological assays

The indirect fluorescent antibody (IFA) procedure remains the most widely used technique for the serodiagnosis of HME and human anaplasmosis, but other techniques are now being assessed, with variable success (Walker 2000; Walls et al. 1999; Aguero-Rosenfeld et al. 2000; Brouqui et al. 2001; Childs et al. 1999; Dawson et al. 1990). Because of the high degree of cross-reactivity between *E. chaffeensis* and *E. ewingii*, and *E. chaffeensis* and *A. phagocytophilum*, methods to improve specificity have been attempted, including protein immunoblots and recombinant protein serology. Enzyme-linked immunosorbent assays (ELISA) are extremely sensitive but have not been well developed for these organisms. Important criteria for selecting appropriate serological tests include the sensitivity, specificity, reproducibility, and predictive value. No careful assessment of the IFA method for testing *E. chaffeensis* antibodies has been conducted, but some analyses suggest a minimum sensitivity of 88 percent for IgG IFA and 86 percent for IgM IFA; specificity is not known, and cross-reactions with *A. phagocytophilum*, *Rickettsia* spp., *C. burnetii*,

Brucella spp., *Borrelia burgdorferi*, Epstein–Barr virus (EBV) infection, and rheumatoid factors are known to occur (Dawson et al. 1990). Much more study has been conducted on these features of IFA serology for *A. phagocytophilum* antibodies (Bakken et al. 2002). Overall, the sensitivity of IFA for human anaplasmosis is reported to be between 82 and 100 percent for IgG IFA and 17 and 37 percent for IgM IFA. The overall specificity also varies from 82 to 100 percent for both IgG and IgM IFA; however, significant cross-reactivity with *E. chaffeensis* confounds specificity and requires that IFA for both *A. phagocytophilum* and *E. chaffeensis* be performed; a four-fold higher titer is suggestive of the serodiagnosis. Unfortunately, a small proportion of patients have antibodies of similar titers for both agents that do not allow a definitive serodiagnosis. Another consideration for serological testing of human anaplasmosis is the frequent coinfection with *Borrelia burgdorferi*. It has still not been resolved whether *A. phagocytophilum* can also elicit a positive serum test for Lyme disease in the absence of *B. burgdorferi* infection. As for all serological tests, there are a number of conditions that have also resulted in false-positive serological results, including Rocky Mountain spotted fever, murine typhus, Q fever, EBV infection, rheumatoid factors, antinuclear antibodies, and antineutrophil cytoplasmic antibodies (ANCA).

Most samples should be tested for both IgG and IgM antibodies, the latter after removal of IgG from an aliquot of serum. While it is advocated that specific diagnostic titers be established by individual laboratories or according to the manufacturer's instructions for kits, the most useful criterion for a definitive serodiagnosis is the demonstration of a four-fold increase in titer between acute and convalescent sera, with a minimum titer of at least 64 or 128. When a single serum is all that is available, a single high titer, usually 128 or greater, provides some level of serologic confidence. While *E. chaffeensis* and *A. phagocytophilum* have only recently been described as human infections and prior serologic assays used surrogate antigens, the use of specific diagnostic antigens is encouraged to minimize false-negative results. Unfortunately, *E. ewingii* has not yet been cultivated in vitro; thus, all serologic tests for this agent are based upon cross-reactions with the related *E. chaffeensis* or *E. canis*. Up to 40 percent of patients with HME and human anaplasmosis have detectable antibodies at presentation, and nearly 100 percent are seropositive within 1 month of onset (Dawson et al. 1990; Bakken et al. 2002).

A number of investigators have assessed recombinant proteins as potential specific serological tools for HME and human anaplasmosis (Lodes et al. 2001; Unver et al. 2001a; Magnarelli et al. 2001; Alleman et al. 2000; Tajima et al. 2000; Ijdo et al. 1999; Yu et al. 1999; Zhi et al. 1998). While these investigations hold some promise, none has proven significantly superior to IFA, and the antigenic variability of the major immunodominant antigens (pfam01617.8, Surface_Ag_2 proteins) confounds selection of a single protein that would be effective broadly.

Factors for consideration in serologic testing include the predictive value of positive and negative tests that are based upon the sensitivity, specificity, and prevalence of the infection in the population to be tested. Unfortunately, the precise prevalence for these infections is not known and is probably significantly underestimated by current national reporting practices. Based upon prevalence data even in highly endemic areas, the positive predictive value conducted in the absence of any additional selection of the population would be unacceptably low, under 1 percent. Thus, all sera obtained for this testing must be carefully selected only from patients with a reasonably high probability of infection. This selection criterion has the effect of increasing the prevalence of infection in the tested population and will significantly improve the positive predictive value. Likewise, a negative test under these circumstances also provides very valuable information.

Molecular diagnostic assays

The real revolution in diagnosis of infections by *E. chaffeensis*, *E. ewingii*, and *A. phagocytophilum* has resulted from the application of PCR amplification of organism-specific nucleotide sequences (Anderson et al. 1992a; Chen et al. 1994a; Buller et al. 1999). The same genes that have been extensively used for phylogenetic and taxonomic purposes are also often used as diagnostic targets. The process of nucleic acid amplification is also highly sensitive, theoretically increasing the starting number of target sequences more that one million times to a level that can be easily detected by routine electrophoresis in agarose gels. The molecular size of the amplified DNA can be compared to a known control for specificity, or a highly specific nucleotide probe can be used in a Southern blot method to further enhance specificity. Methods to improve diagnostic sensitivity also include the selection of targets that are present in multiple copies in the *Ehrlichia* or *Anaplasma* genome.

A variety of gene targets have been applied for diagnosis of HME, including the *E. chaffeensis rrs* (16S rRNA gene) (Anderson et al. 1992b), *groESL* operon (Sumner et al. 1997), *gltA* (citrate synthase) (Inokuma et al. 2002), *p28* multigene family conserved regions (Ohashi et al. 1998), *gp120*, and *nadA* (Carpenter et al. 1999), among others. The advantage of the *p28* family (pfam01617.8, Surface_Ag_2 protein gene) is that 21 distinct copies in the genome possess highly conserved sequences that can be targeted for enhanced analytical sensitivity. However, an important feature of these diagnostic tests is the ability to identify infected individuals

regardless of the analytical sensitivity of the assay applied. For *E. chaffeensis rrs* PCR, the overall sensitivity has been estimated at between 60 and 90 percent (Anderson et al. 1992b; Everett et al. 1994). For *E. ewingii*, little information is available about the sensitivity and specificity of molecular diagnostics (Buller et al. 1999). The limited numbers of human infections have been identified based upon amplification of *rrs* with universal primers followed by sequence analysis. However, specific regions in the *rrs*, as well as sequences of the *groESL* and *p28* genes, have been published and should provide good alternatives for development of highly specific and sensitive assays (Paddock et al. 2001; Sumner et al. 2000; Gusa et al. 2001).

Similarly, the diagnosis of human anaplasmosis is often procured using molecular tests, including targets on *rrs*, *groESL*, *gltA*, *ankA*, and *msp2* (*p44*, HGE-44), among others (Chen et al. 1994a; Edelman and Dumler 1996; Sumner et al. 1997; Inokuma et al. 2002; Walls et al. 2000; Ijdo et al. 1998). As for *E. chaffeensis*, the Msp2 (pfam01617.8, Surface_Ag_2 protein) gene family includes at least 22 and perhaps more than 52 paralogs in the *A. phagocytophilum* genome (Scorpio et al. 2004), a desirable diagnostic target. The *rrs* PCR has been estimated to be at least 60 percent sensitive (Edelman and Dumler 1996; Horowitz et al. 1998); however, PCR based upon the multicopy *ankA* doubled the number of detections among a seropositive cohort, confirming the significant improvement in diagnostic sensitivity with a multicopy gene target (Walls et al. 2000).

Culture-based assays

Both *E. chaffeensis* and *A. phagocytophilum* have been recovered by in vitro cultivation methods from whole blood or isolated leukocytes from infected humans (Dawson et al. 1991; Goodman et al. 1996). *E. ewingii* has still not been cultivated in vitro. As in vitro methods for primary recovery of these agents from patients' blood requires at least several days to several weeks of active incubation in cell culture, these methods are not usually applicable to routine diagnostic laboratories (Horowitz et al. 1998). Regardless, culture methods are a mainstay of bacterial diagnosis, and the recovery of isolates provides a useful reference for investigation of variants and their disease-causing properties. *E. chaffeensis* is ordinarily isolated in cultures of peripheral blood mononuclear cell fractions incubated with the canine histiocyte cell line, DH82. Other cell lines have been used, including THP1, HL-60, U937, and others, but most isolates have been recovered in DH82 cells. Initially, recovery times were expected to require 30 days or longer, but improving experience has reduced that interval to approximately 10–14 days. Cell cultures are examined two or three times weekly by Romanowsky stains, by immunofluorescence using specific antibodies, or by PCR. When visualized by Romanowsky stains or immunofluorescence, the culture can be expanded and stocks prepared for frozen storage or definitive confirmation of species by PCR and sequence analysis of several genes.

A. phagocytophilum can be cultivated from human peripheral blood as well (Goodman et al. 1996; Asanovich et al. 1997). The most frequent cell line used for primary inoculation is HL-60, a human promyelocytic leukemia cell line. Other cells infrequently used include THP1 and KG-1. Recovery times vary but tend to be shorter than for *E. chaffeensis*, with the average culture recovery requiring approximately 7–10 days. One advantage of the HL-60 cell line is that it is maintained as suspensions and is not highly susceptible to the toxic effect of lysed erythrocytes as is the DH82 cell line. Thus, a simple protocol for recovery of *A. phagocytophilum* involves direct inoculation of a small volume of ethylenediaminetetraacetic acid (EDTA)-anticoagulated whole blood into a culture of HL-60 cells.

SUSCEPTIBILITY TO ANTIMICROBIAL AGENTS

Physical stability and chemical inactivation

Ehrlichiae are highly sensitive to environmental conditions, as they are unable to survive outside of the host cell for long periods of time. Long-term maintenance is usually achieved by maintaining highly infected cultured cells in $\geqslant$30 percent serum with 10 percent DMSO at -70°C, or preferably in liquid nitrogen. Purification of individual bacteria from host cells poses even greater challenges because of the tenacity with which the bacteria bind to host vacuolar membranes and their associated proteins and nucleic acids. Physical inactivation with ordinary laboratory disinfectants (10 percent bleach, 70 percent ethanol, etc.) or heat inactivation (autoclaving) are highly effective.

Sensitivity to antibiotics

The in vitro antibiotic susceptibility of *Ehrlichia chaffeensis*, *Anaplasma phagocytophilum*, and *Neorickettsia* sennetsu have been determined (Rikihisa 1991a; Brouqui and Raoult 1992; Klein et al. 1997; Maurin et al. 2003). Doxycycline and rifampin exert bactericidal effects whereas chloramphenicol, erythromycin, cotrimoxazole, penicillin, and gentamicin are not inhibitory. Ciprofloxacin was bacteriostatic for *E. chaffeensis* only at high concentrations but very effective against *E. sennetsu*. Other fluoroquinolones, such as trovofloxacin, may be effective in vitro against *A. phagocytophilum* (Klein et al. 1997), but a mutation in the quinolone-resistance-determining region of *gyrA* (DNA gyrase

gene) in *Ehrlichia* spp. makes these resistant to most or all drugs in this class (Maurin et al. 2001). Similarly, both *Anaplasma* and *Ehrlichia* spp. seem to be highly resistant to even new-generation macrolides. Practical in vivo experience with antibiotics gained during the treatment of a wider range of human and veterinary diseases caused by the ehrlichiae is in agreement with the in vitro data (Dumler and Bakken 1995). Doxycycline is generally effective when given in an early stage of infection. Tetracyclines have also been used to eliminate *W. pipientis* from arthropods to demonstrate their role in various manifestations of cytoplasmic incompatibility (Holden et al. 1993), and trials for reduction of inflammatory sequelae that results from nematodes containing *Wolbachia* in lymphatic filariasis also show promise (Hoerauf et al. 1999). In vivo resistance of *Ehrlichia* and *Anaplasma* spp. to chloramphenicol, coupled with in vitro inefficacy and anecdotal evidence of chloramphenicol failure in patients, suggests it is prudent to use doxycycline rather than chloramphenicol, especially given the potential for fatal outcome.

Treatment

All members of *Anaplasmataceae*, including the three important human pathogens *E. chaffeensis*, *A. phagocytophilum*, and *E. ewingii*, are susceptible to antibiotics. Prompt administration of appropriate therapy is critical to minimize the degree to which host inflammatory and immune mechanisms are driven toward pathologic consequences and severe disease. Thus, doxycycline is the drug of choice for treating HME, *ehrlichiosis ewingii*, and human anaplasmosis, although the empirical success of rifampin in the treatment of human anaplasmosis during pregnancy (Buitrago et al. 1998) also agrees with in vitro susceptibility data. Doxycycline is preferred because of the twice per day dosage and the very high therapeutic window. Although many pediatricians have been reluctant to use doxycycline in children under 8 years of age, the American Academy of Pediatrics now advocates the use of doxycycline to treat ehrlichiosis (and anaplasmosis) (American Academy of Pediatrics 2000). No clinical studies have examined the efficacy of either doxycycline or rifampin, but the potential adverse effects of doxycycline in pregnancy have led to the successful use of rifampin in that situation. Adults should receive 200 mg of doxycycline twice per day, orally, every 6 h. Children should receive 3–4 mg/kg of doxycycline every 24 h in two doses, not to exceed 300 mg per dose. Patients who are unable to take doxycycline orally should receive intravenous treatment. The duration of therapy should extend for at least 3–5 days after defervescence, for a total of not less than 5–7 days, but many prefer to treat for a total of 21 days to provide adequate therapy for the potential of cotransmitted *B. burgdorferi* with *A. phagocytophilum*. Some standard therapies for Lyme disease (amoxicillin or ceftriaxone) are not effective for anaplasmosis or HME. Clinical improvement is rapid in properly treated patients. Most patients with HME or human anaplasmosis report resolution of fever and other clinical manifestations within 48–72 h. Relapse or reinfection has only rarely been reported.

Prevention

Because tick-borne *Anaplasmataceae* infections occur when humans intrude on areas infested with reservoir animals and ticks, the best prevention is avoidance of such areas. Control of ticks, small mammal and rodent populations, and deer populations is probably important for prevention, but studies to extend these findings from Lyme disease have not been conducted. Personal protective measures include clothing treated with permethrin and diethyltoluamide may reduce the frequency of tick bites. Prompt detection and removal of ticks is a useful and cost-effective preventive measure. People who must enter tick-infested areas should wear light-colored clothing to facilitate detection of ticks. Embedded ticks should be removed as soon as possible as a short interval is required prior to transmission from the tick into the host. Ticks may be removed with tweezers by grasping at the skin surface and pulling with slow, steady traction. Careful disinfection of the attachment site with soap and water is also a useful precaution.

TICK TESTING AS A PREDICTOR OF DISEASE

An emerging concept in tick-transmitted infections is the determination of whether an attached tick is infected, and the use of this information to guide in prophylactic therapy. A rational approach requires information about whether prophylactic therapy is useful and the likelihood of transmission occurring from an infected tick. The latter concept also requires knowledge regarding the interval of tick attachment needed prior to transmission of *Ehrlichia* or *Anaplasma* spp. Experimental transmission of *E. chaffeensis* by infected *A. americanum* ticks has been conducted, but data regarding the 'grace period' have not been generated. Although *A. americanum* is also the suspected vector of *E. ewingii*, experimental and timed transmission studies have not been conducted. Transmission of *A. phagocytophilum* from infected ticks to mice begins within 24 h, when as little as 30 percent to as many as 67 percent of mice acquire infection (Hodzic et al. 1998; des Vignes et al. 2001). Thus, unlike the situation for *B. burgdorferi*, daily tick checks and removal may not be adequate to prevent transmission. As the majority of these studies were conducted by cofeeding multiple ticks on a single susceptible host, the proportion of ticks capable of trans-

mitting *A. phagocytophilum* is not known. In fact, the US military maintains a facility for testing ticks removed after attachment to soldiers. The prevalence of *E. chaffeensis* in attached *A. americanum* is 15 percent, and of *A. phagocytophilum* in *I. scapularis* is 2 percent (Stromdahl et al. 2001); regardless, both rates far exceed the reported numbers of cases of either HME or human anaplasmosis in the US military services, suggesting that this approach poorly correlates with subsequent disease. Moreover, few data are available regarding the prophylactic efficacy of treatment during the incubation period of HME and human anaplasmosis, although a single patient who received prophylactic doxycycline after an *A. americanum* bite seroconverted to *E. chaffeensis* and never became ill. Currently, too little information is available to make specific recommendations regarding the feasibility of tick testing to guide decisions about antibiotic prophylaxis.

INTRODUCTION

Coxiellia burnetii is an intracellular, gram-negative acidophile bacterium that replicates in high numbers within the phagolysosome of its eukaryotic host and is the etiological agent of Q fever. An Australian physician, Edward Derrick, described a febrile illness amongst abattoir workers in 1935 as 'query (Q) fever' (Derrick 1937). Derrick's initial attempts to isolate the causative agent proved unsuccessful. However, clinical material obtained from ill workers in a meat-packing plant in Brisbane, Australia reproduced the disease in laboratory guinea pigs. Infected guinea pig liver sent to MacFarlane Burnet, confirmed the disease in laboratory animals. Impression smears of infected mouse spleen revealed large intracellular vacuoles containing small rod-shaped organisms that Burnet and Freeman characterized as rickettsia. At the same time, in Hamilton, Montana, an unexpected febrile illness was also produced in guinea pigs during a Rickettsia spotted fever study. The causative agent was referred to as 'Nine Mile agent' and later named *Rickettsia diaporica* because, unlike other rickettsial agents, it was filterable (Davis and Cox 1938). All attempts to grow the agent on axenic media failed, but during these studies a febrile illness displayed, through a laboratory-derived infection, a confirmed link between Q fever and Nine Mile agent. Blood from one of the patients produced a similar febrile illness in guinea pigs. Davies and Cox demonstrated that convalescent guinea pigs previously infected with Burnet's spleen sample were immune to challenge by the Nine Mile agent, thus demonstrating antigenic crossreactivity between the two agents. In 1938, the causative agent was assigned a new genus and species name, *Coxiella burnetii*, in recognition of the work by Cox and Burnet (Weiss 1992).

CLASSIFICATION

In the past, the taxonomy of coxiella was closely linked to the rickettsiae and was principally based on comparisons of phenotypic characteristics. More so than in other bacteria, historical and environmental considerations also played important roles in classification. In the eighth edition of *Topley & Wilson*, the principal genera discussed were *Rickettsia*, *Rochalimaea*, and *Coxiella*. More recently, classification of rickettsiae and other bacteria have been increasingly based on DNA sequences, particularly on 16S and 23S rDNA sequence comparisons. The genera *Rickettsia* and *Ehrlichia* belong in distinct branches of the α subdivision of Proteobacteria (Roux and Raoult 1995; Stothard and Fuerst 1995), whereas *Rochalimaea* belong in the α_2 subdivision and are most closely related to the agrobacteria and rhizobacteria. Recent phylogenetic analysis of the 16S rRNA sequences has resulted in the reclassification of

C. burnetii to the γ subgroup of Proteobacteria, thus establishing it being closely related to *Legionella pneumophila* and *Wolbachia persica* (Weisburg et al. 1989). While *Rickettsia* species replicate in the host cytoplasm, *C. burnetii* displays both phenotypic and genetic similarities to *L. pneumophila*, including intracellular growth in a membrane-bound vacuole and sequence similarities for a variety of genes (Mo et al. 1995).

HABITAT

Coxiella burnetii is a category B bioterrorism agent that is highly infective to both humans and livestock (Martin and Raoult 1999). The agent is widespread in the natural environment due, in part, to its high degree of stability under conditions unfavorable for growth and to its transmission from animal to animal and to humans, primarily by aerosol (Raoult and Marrie 1995). It has been reported from virtually every part of the world. A tick host (*Dermacentor andersonii*) has been implicated to play an important role in natural infection, but many vertebrate animals are also heavily infected and play a role in transmission. *C. burnetii* is often an occupational disease in individuals working in slaughterhouses. The bacterium is particularly abundant in the placenta of a parturient animal. Parturient cats in a household can also cause infection.

MICROENVIRONMENT AND MORPHOLOGY

C. burnetii is a unique bacterium that combines adaptation to the acid environment of the phagolysosome with a developmental cycle that includes transverse binary fission and sporogenesis. The developmental cycle is described in detail by McCaul and Williams (1981). In addition to the schematic representation of the cycle, the great variety of forms in a purified preparation and a cell undergoing cell division and containing a spore is shown. The usual smears of *C. burnetii* infected cells display a great variety of forms; the cells which have not yet divided are usually small rods (approximately 0.3 by 1.0 μm) which double in size or develop a spore at one end or both. The smears also contain spores in various stages of development. In contrast to other rickettsiae, coxiellae have some gram-positive surface components but also, on repeated cultivation in the laboratory, may display lipopolysaccharide (LPS) phase variation. Phase I cells are infectious for animals, while phase II cells usually appear upon repeated cultivation in the yolk sac of chicken embryos. Phase II cells do not have the full complement of properties required for survival in macrophages. The adaptation to an acid environment is demonstrated through detecting many metabolic activities only when the pH is 5 or lower (Redd and Thompson 1995).

LABORATORY ISOLATION, CULTURAL CHARACTERISTICS, AND GROWTH REQUIREMENTS

The yolk sacs of embryonated chicken embryos have proved a good medium for the isolation of Q fever. Eggs are inoculated when the embryos are 5–7 days old. The top of the egg above the air sac is surface-sterilized and a hole is punched aseptically. A 0.2–0.4 ml inoculum is delivered with a 22-gauge needle long enough (2–3 cm) to penetrate into the yolk sac. The *Coxiella* inoculum is adjusted to kill 30 percent of the embryos in 5–8 days. Suspending fluids for such harvests are brain–heart infusion (BHI) broth or sucrose phosphate glutamate (SPG) solution, consisting of 0.22 M sucrose, 0.1 M potassium phosphate, 5 mM potassium glutamate, pH 7.0. The pools of yolk sacs and their suspending medium are homogenized in bottles containing 5 mM glass beads, dispensed in vials and used as inocula or purified for use in physiological or antigenic studies. For further details of these procedures, see Dasch and Weiss (1992).

Cell cultures offer many opportunities for rapid isolation and identification of coxiella from infected animals or patients. The shell vial culture technique has the advantage that it concentrates a moderate volume of inoculum over a small monolayer of highly susceptible cells on a coverslip. It enhances the infection by centrifugation (usually at 700 *g* for 1 h) prior to incubation. After centrifugation, the supernatant is removed and replaced by an appropriate medium, such as Eagle's minimal essential medium (MEM) containing 10 percent fetal bovine serum. If several vials are treated with the same inoculum, a duplicate coverslip can be examined a few days after inoculation and the rickettsiae identified by the indirect fluorescent antibody method. After a satisfactory level of infection is reached, the remaining vials can be used for passage of the coxiella into tissue culture flasks for the production of larger volumes. This method has been used to identify *C. burnetii* from human blood in cases of acute disease and suspected chronic endocarditis (Musso and Raoult 1995).

Isolation of *Coxiella* by plaque formation is usually undertaken on monolayers of chicken embryo fibroblasts but can also be done on L929 or Vero cells (Figure 1). The tissues are obtained from decapitated 10-day-old chicken embryos, thoroughly minced in Earle's balanced salt solution (EBSS), and the cells are further separated from each other by digestion with 0.25 percent trypsin for 20 min at 37°C. Trypsinization is terminated by the addition of fetal bovine serum. Clumps are removed by filtration over sterile cheesecloth and the isolated cells are sedimented by centrifugation and resuspended in MEM containing 10 percent fetal bovine serum. The suspension is dispensed into 25-cm^2 tissue culture flasks, 5 ml per flask, and confluent monolayers are allowed to form by incubation overnight at 37°C. The samples to be

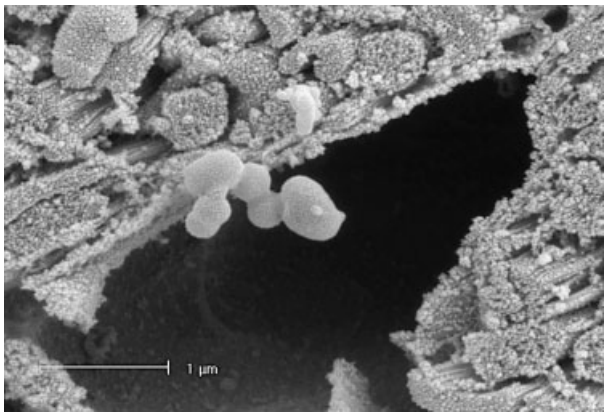

Figure 1 *Scanning electron micrograph of* C. burnetii *cells with dewaxed sections of guinea pig heart 9 days after aerosol infection. Courtesy of B. Dowestt, S. Lever and G. Lloyd, HPA Porton, UK*

plaqued are diluted serially in BHI and, after the supernatant fluid has been removed, 0.1 ml volumes are added to the monolayers. Plaquing efficiency is increased by gentle rocking of the flasks for 60 min or by moderate centrifugation of the inoculum over the cells. Finally, the cultures are overlaid with an appropriate medium (such as RPMI 1640 or Medium 199 containing glutamine and 0.8 percent agarose). Spotted Fever Group rickettsial plaques are recognized 4–7 days post-inoculation and are 2–3 mm in diameter. Plaque isolation is particularly valuable for the isolation of phase I and phase II variant forms of *C. burnetii*.

For the mass cultivation of coxiellae, irradiated mouse L929 or Vero cells are often used in large flasks. When growth is sufficiently abundant, the cells are harvested with glass beads. The suspension is then centrifuged and the pellet resuspended in SPG for freezing or in BHI for further propagation. For additional information, see Dasch and Weiss (1992) and Williams et al. (1992a)

MORPHOLOGY – GENOME AND PLASMIDS

For many years, *C. burnetii* was thought to be relatively homogeneous, except for antigenic phase variation, and the same organism was believed to cause both acute and chronic disease. Recent genetic studies have shown that *Coxiella* is not homogeneous, but it appears that the same genotype can cause both types of disease. *Coxiella* isolates exhibited 14 distinct restriction fragment length polymorphism (RLPF) patterns of genomic DNA by pulsed field gel electrophoresis (PFGE), giving a genomic size of 1.4–1.9 Mb, in good agreement with the 1.7 Mb estimated by reassociation kinetics (Thiele et al. 1993; Thiele and Willems 1994). The DNA base composition of *Coxiella* is 42 percent G + C. Plasmids have been discovered in *C. burnetii*. Initially, six different genomic groups were distinguished among American isolates by the type of plasmid and RFLP pattern obtained using *Eco*RI or *Bam*HI digested total DNA separated on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and silver stained. A 36 kb plasmid, QpH1, was present in three genomic groups with isolates from ticks or animals or causing acute illness in humans, the 39 kb plasmid, QpRS, was present in an isolate causing chronic disease, and the 51 kb plasmid, QpDG, was present in feral rodent isolates of unknown pathogenicity. Another chronic disease isolate group contained both QpRS and QpH1 related plasmid sequences integrated into the chromosome. No unique sequences common to the plasmidless isolates and QpRS have been found that might cause 'chronic' disease. About 30 kb of core plasmid sequence is conserved in all genomic groups, whereas the remainder is plasmid specific. Isolates varying only in phase state or passage history exhibit minimal differences. These plasmid sequences are not known to encode virulence factors but their conservation in all genetic groups suggests that they are essential to the survival of *C. burnetii*. European isolates were also found to contain QpH1 sequences whereas a Namibian isolate contained QpRS sequences. More recently, the association of specific plasmid type with pathogenicity has been questioned as only nine of 30 European isolates, including both acute and chronic isolates, had sequences specific to QpH1 (Stein and Raoult 1993; Thiele and Willems 1994). Similarly, a new 33.5 kb plasmid, QpDV, found in isolates from both acute and chronic disease, has been described (Valkova and Kazar 1995). Both the 90–95 percent DNA–DNA homologies exhibited between different genomic groups and the greater than 99 percent 16S rDNA sequence similarity in different isolates of *C. burnetii* argue for their retention as a single species (Hendrix et al. 1991; Stein et al. 1993).

Thirty-seven open reading frames (ORF) have been identified in QpH1 (Thiele and Willems 1994). ORF cbhE′ encoded a 39.4 kDa hydrophilic protein unique to QpH1. ORFs related to *Pseudomonas* proteins, ferripyochelin-binding protein (FBP), 32.4 kDa protein, and replication proteins, to *Escherichia* DNA helicase I and SopA protein, to *Agrobacterium* replication protein RepB and to bacteriophage λ tail assembly protein K were recognized. FBP plays a role in iron acquisition and may be a virulence determinant in *Pseudomonas*. QpH1 proteins with homology to the F plasmid partition proteins SopA and SopB were found to be also conserved in the plasmids QpRS, QpDV, and QpDG, but absent in plasmidless isolates (Lin et al. 1995). The QpRS-specific gene *cbbE′* was not found in plasmidless isolates and encoded a 55 kDa protein which was a surface-exposed outer-membrane protein of unknown function.

The rRNA operon of *C. burnetii* is organized in the order 16S–23S–5S rDNA (Afseth et al. 1995). The 16S–23S rDNA spacer is *Coxiella* specific and encodes tRNA

genes for isoleucine and alanine. The 23S rDNA contains an unusual 444 bp intervening sequence which has a stem-loop structure due to flanking 28 bp inverted repeats. The absence of intact mature 23S rRNA suggests the loop is excised. Approximately 19 copies of a 1450 bp repetitive element were found in *C. burnetii*, including one associated with the *groESL* heat shock protein operon (Hoover et al. 1992). The element had terminal seven and internal 12 bp inverted repeats at each end and encoded an ORF for a 367 amino acid basic polypeptide with a DNA binding helix-turn-helix and a leucine zipper motif, suggesting it may be a transposase. Ten French isolates with eight different PFGE patterns each contained this repetitive element (Thiele and Willems 1994). Three independent copies of this element each had additional nonhomologous internal 85–93 bp inserts with strong dyad symmetry demarked by identical 7 bp inverted repeats (Hoover et al. 1992). The *gltA-sdh* intergenic region was found to contain three similar, nearly perfect, inverted repeats (Heinzen et al. 1995). A probe to the terminal 7 bp inverted repeat sequence hybridized to multiple sequences in four different genomic groups. Whether the inverted repeat sequences have important regulatory functions is unknown.

Although *C. burnetii* is rather unique in its life-style, it retains many genetic functions that are organized similarly to those of other γ Proteobacteria such as *Escherichia coli*; this permits their cloning and identification by functional complementation of mutants and by sequence homology. Characterized genomic regions include a TCA cycle gene cluster similar in arrangement to that of *E. coli* (Heinzen et al. 1995) and the aspartate carbamylase catalytic subunit. The *sdhCDAB* gene cluster encodes succinate dehydrogenase enzyme complex and is adjoined by the 2-oxoglutarate dehydrogenase and citrate synthase genes. Other characterized genes express iron containing superoxide dismutase, homologs of *E. coli* heat shock GroES and GroEL proteins, the heat shock protein DnaJ, and the *mucZ* gene product which has some homology to *dnaJ* and activates capsule synthesis in *E. coli*. An autonomous replication sequence was characterized that contains ORFs with homology to genes often found near bacterial chromosomal origins, including *rpmH*, *rnpA*, 9 kDa, and 60 kDa membrane proteins. Some information has been obtained for genes encoding a protein similar to the *Legionella* macrophage infectivity potentiator (Mip) protein (Mo et al. 1995), a protein with homology to bacterial sensor proteins found in two-component regulatory systems (Mo and Mallavia 1994), and a 27 kDa surface-exposed loosely associated outer-membrane protein Com1 (Hendrix et al. 1993). The *rnc* locus of *C. burnetii* contained genes with protein homology to RNAase III, RecO, and Era of *E. coli*; *rnc* suppressed capsule synthesis in *E. coli* even though *C. burnetii* does not contain a capsule. Era is a 35 kDa GTP binding protein that is essential for cell viability. RNAase III is a double-stranded RNA-dependent endoribonuclease. RecO function is involved in DNA recombination and repair.

STRUCTURE–CELL WALL COMPOSITION AND ANTIGENIC PROPERTIES

Consistent with the phylogenetic distance of *Coxiella* from the other rickettsiae, it is antigenically distinct from them. Although the gram-negative cell wall structure and composition of *C. burnetii* have been studied intensively (Williams and Waag 1991), an accurate inventory of the cell wall components and their function is difficult because of the distinct morphological forms present in its complex developmental cycle, the unique virulence-associated LPS phase variation, the difficult physical solubility properties of individual components in the cell envelope, and the range of analytical methods used in cell fractionation. The structure of the LPS is not completely known, but phase I and II differences in chemical composition and size are compatible with a smooth to rough transition where the O side polysaccharide undergoes significant truncation while the core region which contains KDO and lipid A is retained. The neutral sugars virenose and dihydrohydroxystreptose are the major antigenic sugars in the O side chain but they are not unique to *Coxiella*. The branched chain fatty acid composition of the LPS is unique to *Coxiella* although other pathogenic bacteria share some components. Phase I LPS is relatively nontoxic compared with *Salmonella* LPS.

Formalin-treated phase I whole cell vaccines have been widely used in animals and are effective in man, while phase II whole cells are considerably less effective (Ackland et al. 1994). Unfortunately, the phase I whole cell vaccines occasionally induce erythema, induration, granulomas, and sterile abscesses in some individuals, and such severe local and systemic reactions in immune individuals that they must be prescreened by skin test. Consequently, a chloroform–methanol residue (CMR) vaccine was developed which retained good efficacy for animals and man and fewer adverse reactions (Williams et al. 1992b; Fries et al. 1993). This vaccine retains the LPS and the majority of cellular proteins, but is greatly reduced in phospholipids. Trichloroacetic acid extracts containing phase I LPS and purified phase I LPS were protective in mice but not phase II LPS or polysaccharide or lipid A fractions of phase I or II LPS (Gajdosova et al. 1994). Phase I cells contain both immunosuppressive and immunostimulatory molecules that are in part disassociated by chloroform–methanol extraction (Williams and Waag 1991; Tokarevich et al. 1993). Both tumor regression and antiviral activity of phase I and CMR fraction have been observed (Zvilich et al. 1995).

Various protein antigens have been identified by radioimmunoprecipitation of surface radioiodinated proteins and immunoblotting (Williams and Waag 1991). The best characterized is a 29 kDa protein P1 present in phase I and II cells, but not in the small dense cell type or endogenous spore (McCaul et al. 1991). It is both immunogenic and protective for animals (Gajdosova et al. 1994; Lukacova et al. 1994). The 29 kDa protein P1 may be identical to the cloned 27 kDa Com1 protein, or several antigenic proteins of similar size are present since another 29 kDa lipoprotein, P2, has also been described. Zhang et al. (1994) also found a 67 kDa outer-membrane protein which was protective in guinea pigs and mice. The conserved 62 kDa protein of *Coxiella* is homologous to the widely conserved chaperonin 60 heat shock protein GroEL. Its expression is regulated by heat in *E. coli* and by heat or 10 percent ethanol in acid-activated *Coxiella*. It is present on the surface of phase II but not phase I cells. The 62 kDa protein is immunogenic since it is recognized by sera from acute and chronic Q fever patients, but it is probably not protective. Whether combinations of purified LPS and antigenic protein or peptide components will offer advantages over CMR or whole cell vaccines is unresolved.

TRANSMISSION, PATHOGENESIS, AND CLINICAL SYMPTOMS

Transmission

Q fever is usually transmitted by the inhalation of small particle aerosols that originate from infected animals. Q fever is enzootic among domestic animals, especially sheep, cattle, and goats. Infected cats have also been reported as sources of infection (Marrie 1988). *C. burnetii* is found in high concentrations within the placenta of infected females and is shed at parturition. *C. burnetii* is extremely stable under environmental conditions, is highly infectious, can be broadly disseminated by dust, dried manure, or other materials, and presents an infectious hazard in areas where animal husbandry is practised. Diseases occur sporadically, but outbreaks are common, particularly among abattoir workers. Outbreaks of Q fever have also occurred in research facilities where sheep are used as experimental animals (Meikeljohn et al. 1981). Consumption of raw milk from infected animals has also been responsible for a number of human infections (Fishbein and Raoult 1992).

The incubation period varies from 9 to 28 days, averaging 18 to 21 days and is dependent on the number of organisms that initially infect the patient. Onset is abrupt with fever, severe headache, chills, severe malaise, myalgia, confusion, sore throat, chills, and, often, chest pains. Fever may rise to 40°C (104°F) and may persist for 1 to >3 weeks. A nonproductive cough and X-ray evidence of pneumonitis often develop during the second week of illness in 30 to 50 percent of symptomatic infection. In severe cases, lobar consolidation usually occurs, and the gross appearance of the lung may resemble that of bacterial pneumonia. Histological changes in Q fever pneumonia resemble those of psittacosis and some viral pneumonia as demonstrated by an intense interstitial infiltrate around the bronchioles and blood vessels which extends into the adjacent alveolar. The bronchial luminar may also show extensive invasive polymorphonuclear leukocytes. Approximately a third of patients with protracted Q fever develop hepatitis, characterized by fever, malaise, hepatomegaly with right upper abdominal pain, and possibly jaundice. Liver biopsy specimens show diffuse granulomatous changes, and *C. burnetii* may be identified by immunofluorescence. Headache or respiratory signs are frequently absent. Lobar pneumonia may be particularly severe in aged or debilitated patients. In general, most patients will recover to good health within a few months without treatment. Approximately 1–2 percent patients who contract Q fever may die.

There are also several forms of chronic Q fever with chronic hepatitis and endocarditis. Chronic Q fever is characterized by an infection that lasts longer than 6 months. Patients who have had acute Q fever may develop the chronic form as soon as 1 year, or as long as 20 years, after initial infection. A serious complication of Q fever is endocarditis, generally involving the aortic heart valve and less commonly the mitral valve (Figure 2). Most people who develop chronic Q fever have a pre-existing valvular heart disease or have a history of vascular graft. Transplant patients, cancer suffers, and those with kidney disease are also at risk of developing chronic Q fever. As many as 65 percent of persons with chronic Q fever may die of the disease.

Those patients who fully recover from infection may possess lifelong immunity against reinfection.

Pathogenesis

C. burnetii parasitizes the acidified phagolysosomal compartment of its host cells (Baca et al. 1994). Both catabolic and anabolic activity, including the synthesis of DNA and protein, can be measured in defined medium at acidic pH (Thompson 1991; Redd and Thompson 1995). Following acid activation 34, 24, and 12 kDa proteins are exported by *Coxiella* but their function is unknown. The *Coxiella* 24 kDa Mip protein possesses peptidyl-prolyl-*cis-trans*-isomerase activity and is an exported protein, suggesting that it has a role in protein folding and trafficking (Mo et al. 1995). Whether Mip is one of the exported acid activation proteins is unknown. In *Legionella* and *Chlamydia*, Mip proteins have been found to have roles in establishing infection of host cells. Phase II cells more readily attach to L cells than phase I organisms and while purified phase I LPS did not inhibit attachment of *Coxiella* to host cells, protease treatment of host cells abolished attachment (Baca et al. 1993). Heat- or formaldehyde-inactivated *Coxiella* could attach and enter cells whereas inhibitors of host cell phagocytosis (such as NaF and cytochalasins B and D) abolished rickettsial uptake. This suggests *Coxiella* is passively phagocytosed. *C. burnetii* also binds C-reactive protein, complement components, and normal immunoglobulin which may facilitate cell infection in vivo (Williams et al. 1989). *Coxiella* adhesins or proteins essential for survival in the phagolysosome have not been identified conclusively, although roles for superoxide dismutase, catalase, and acid phosphatase have been suggested (Baca et al. 1994). The acid phosphatase activity blocks superoxide anion production by stimulated human neutrophils. In *Salmonella*, acid phosphatase encoding genes are regulated by *phoQ* and *phoP* genes which enhance survival in macrophages. A similar sensor-like protein has been described in *Coxiella* (Mo and Mallavia 1994). Phase II cells are sensitive to complement-mediated killing while phase I cells are not, suggesting that phase I LPS mediates resistance. Phase I LPS may mask underlying antigens from exposure to the immune system since ^{125}I-labelled antiphase II antibodies bound 10- and 44-fold more to trichloroacetic acid-extracted phase I cells and to phase II cells, respectively, than to native phase I cells (Hackstadt 1988), thus explaining, in part, the slow phase I serological response in *Coxiella* infection. LPS is an important virulence factor since intrastrain LPS phase I, intermediate, and phase II variants differ significantly in virulence in guinea pig and mouse models (Kazar et al. 1993).

LABORATORY DIAGNOSIS

There are significant risks associated with direct isolation of *C. burnetii* and any attempts should be undertaken under biosafety level three laboratory containment. Direct isolation of *C. burnetii* is successfully achieved through the inoculation of cell monolayers of Vero cells or J774.16 mouse macrophages cells in shell vials (Raoult et al. 1991; Spyridaki et al. 2002). The direct identification of *C. burnetii* is most easily accomplished by direct immunofluorescent antibody staining of organisms in biopsies or after isolation (Musso and Raoult 1995). A monoclonal antibody suitable for this purpose has been described. Alternatively, polymerase chain reaction (PCR), using primers specific for superoxide dismutase, a conserved plasmid sequence, or a large conserved repetitive element (Thiele and Willems 1994; Spyridaki et al. 2002) may be done. Chromosomal DNA and plasmid-based typing has been used extensively to differentiate isolates. Protein profiles and Western blotting of proteins have not been very useful for typing strains, although distinct LPS profiles may be obtained, particularly among phase variants (Kovacova et al. 1994). Monoclonal and polyclonal sera can be used for distinguishing LPS variants (Yu and Raoult 1994).

Most diagnoses of Q fever infection are based on a variety of retrospective serological procedures based on indirect immunofluorescence employing phase I and phase II antigens (Uhaa et al. 1994; Waag et al. 1995; Hamzie et al. 2003). The responses to the different phase I and II antigens is important in establishing a diagnosis and reflects the different clinical presentations of the disease. In acute cases of Q fever, the presence of IgM and IgG phase II antibodies is generally detected during the second week of illness. Evidence of chronic Q fever is demonstrated by the presence of high levels of IgG anti-coxiella phase I antibodies. These antibodies require longer to appear and indicate continued exposure to the bacteria. Increased levels of phase 1 IgG and IgA antibodies indicate the possibility of Q endocarditis (Camacho et al. 1998). More recently, the value of molecular techniques has been evaluated and data indicate that the use of PCR techniques could be of value during the first 2 weeks of the disease and not used 4 weeks post onset, when the serology is highly sensitive. (Fournier and Raoult 2003). This has been extended to the early detection of clinically and histologically silent Q fever endocarditis accidentally diagnosed by PCR targeting eubacterial 16S rDNA on the mitral valve removed after surgery (Issartel et al. 2002).

TREATMENT – SENSITIVITY TO ANTIBIOTICS

Since *C. burnetii* does not multiply in axenic media, animals, embryonated chicken eggs, and cell culture methods have been used for testing antibiotic susceptibility. All of these methods suggest that *C. burnetii* is more resistant to antibiotics like chloramphenicol, erythromycin, and streptomycin. Egg survival and suppression of illness in animals are less useful than growth in tissue culture for gauging whether antibiotics

are bactericidal rather than bacteriostatic. In eggs, clindamycin, erythromycin, viomycin, cycloserine, and cephalothin were ineffective, while rifampicin, trimethoprim, doxycycline, and oxytetracycline were bacteriostatic. Chlorotetracycline-resistant isolates of *C. burnetii* have been isolated by serial passage in eggs in the presence of low concentrations of antibiotic; one Cyprus isolate with enhanced natural resistance to tetracyclines was found.

Suppression of primary shell vial growth in HEL cells of 13 *C. burnetii* isolates was used to evaluate bacteriostatic properties of antibiotics (Raoult 1993). Amikacin and amoxycillin were never effective. Co-trimoxazole, rifampicin, doxycycline, tetracycline, minocycline, sparfloxacin, and quinolones PD127,391 and PD131,628 were always effective. Variable resistance was noted with ofloxacin, pefloxacin, chloramphenicol, ceftriaxone, fusidic acid, and erythromycin. The fluoroquinolones ciprofloxacin, pefloxacin, and fleroxacin were bacteriostatic in eggs and Vero cells (Keren et al. 1994). Assays employing persistently infected dividing L929 cells initially suggested that rifampicin and the quinolones pefloxacin, ofloxacin, and ciprofloxacin were bactericidal but that doxycycline was not. However, this could not be confirmed for any of these antibiotics when cell growth was inhibited by cycloheximide. Using this assay or direct enumeration of viable *Coxiella* exposed to antibiotic for 24 h after infection in P388D1 macrophage cells, the lysosomotropic agents amantadine, chloroquine, or ammonium chloride were used to alkalinize the pH 4.8 *C. burnetii*-containing phagolysosome to pH 5.3, 5.7, or 6.8 (Maurin et al. 1992). Pefloxacin and doxycycline were bactericidal at the more alkaline pH whereas rifampicin was not. Clarithromycin, a macrolide erythromycin derivative that can be tolerated during childhood and pregnancy, exhibited good bacteriostatic activity against four genomic types but it was not tested in the presence of lysosomotropic agents for bactericidal activity (Maurin and Raoult 1993).

Since acute Q fever is often self-limiting, bacteriostatic antibiotics are often effective. A dose of 100 mg of doxycycline taken twice daily for 15–21 days is a frequently prescribed therapy. Chronic Q fever can be managed with bacteriostatic antibiotics but the patient may not be cured unless a bactericidal regimen is employed. Although differential resistance of isolates from chronic disease patients has been noted, this may be due to changes in host cell (tetracyclines) or isolate-specific permeabilities (fluoroquinolones) (Yeaman and Baca 1991). Two different treatment protocols have been successfully evaluated: (1) doxycyline in combination with quinolines for at least 4 years; and (2) doxycycline combination with hydroxychloroquine for 1.5–3 years. The second therapy leads to fewer relapses, but requires routine eye examinations to detect accumulation of chloroquine. Surgery to remove damaged valves may be required for some cases of *C. burnetii* endocarditis. Cotrimoxazole treatment was found to be effective during pregnancy preventing abortion although it did not significantly reduce colonization of the placenta (Raoult et al. 2002).

EPIDEMIOLOGY AND CONTROL

For Q fever, the only known important natural infection mechanism in man is by the inhalation route and human to human transmission has only occurred rarely. Experiments carried out in the 1950s examined the infectious doses by the inhalation route in guinea pigs and man (Tigertt and Benenson 1956; Tigertt 1959) and determined that one organism could initiate infection in the guinea pig and that the infectious dose in man was ten organisms. The incubation period at this level was 17 days and decreased to 10 days with an infecting dose of 10^5 organisms. The agent used was *C. burnetii* AD strain which had been isolated from milk in California. It was found possible to suppress completely any clinical disease in man exposed by the inhalation route with oxytetracyline administered during the incubation period.

C. burnetii is maintained as a zoonotic infection through an extensive reservoir in mammal, bird, and arthropod species. Wild rodents appear to be a significant reservoir and household pets, such as cats, can transmit infections during parturition. Cattle, sheep, and goats are often infected without clinical disease and *C. burnetii* are shed in their feces, milk, and birth products. Workers involved in animal rearing, dairy farming, or animal slaughter therefore have a significant risk (Woldehiwet 2004). Outbreaks have normally resulted from occupational exposure involving veterinarians, abattoir workers, sheep and dairy workers, livestock farmers, and researchers (Marmion and Stoker 1958; Thomas et al. 1995).

Some outbreaks have been extensive and less easily explained and thought to be due to the survival of the organism in the environment, airborne spread, and very low infective dose. Five cases of clinical Q fever were identified in schoolchildren exposed to goats and raw goats milk, and further investigations in 461 pupils revealed 80 who had past evidence of infection (Jorm et al. 1990). The largest outbreak of Q fever in the UK occurred in Birmingham in 1989, 147 cases were identified but none had direct animal contact. Investigations revealed the probable source of the outbreak to be airborne spread of organisms from farmland during gale force winds (Hawker et al. 1998). Other outbreaks have been associated with deployed troops in Bosnia and windborne spread probably from a sheep farm by helicopter down draught air disturbance (Splino et al. 2003). Intriguingly, office renovation and the repeated drilling of contaminated straw-containing boards has been proposed as the source of 95 cases of acute Q fever in an office setting in South Wales (Von Woerden et al. 2004).

A number of measures has been initiated post outbreak or are routinely put in place in endemic areas which range from educating the public to vaccinating research or abattoir workers.

Control

C. burnetii is highly resistant to elevated temperatures, desiccation, osmotic shock, ultraviolet light, and chemical disinfectants (Scott and Williams 1990). Coupled with its infectivity for humans of 1–10 organisms, contamination of food, buildings, and pastures, it has frequently led to human and animal infections. Highly effective disinfectants of suspended organisms were 70 percent ethanol, 5 percent chloroform, and 5 percent EnviroChem, whereas Alcide, sodium hypochlorite, benzalkonium chloride, Lysol, and 5 percent formalin were not. Paraformaldehyde gas and ethylene oxide sterilization of surface-applied organisms was inefficient under low humidity conditions. It is probable that metabolic dormancy at pH 6 and the developmental cycle which generates spores and small dense forms both contribute to the physical and chemical resistance of *C. burnetii* to inactivation.

Control by reducing the risks has been approached by issuing advice to animal workers that, if they have pregnant partners, care should be taken with hygiene after occupational exposure by hand washing and removing contaminated clothing for separate washing.

A vaccine has been developed in Australia and is used for prevention of infection in populations at risk (Marmion et al. 1984).

Introduction

BRIGITTE A. ASKONAS

The publication of this immunology volume as a separate entity in *Topley & Wilson's Microbiology and Microbial Infections* is a welcome innovation and a reflection of extensive progress in our understanding of the immune system in recent decades. Nevertheless there are still enormous gaps in our knowledge that need to be investigated before we will be able to manipulate immune responses predictably to our advantage. Recent advances are widely distributed in numerous different journals and publications, and this makes it difficult to keep up with so much new information relating to the complex and now vast field of immunology. Present knowledge relied on a whole range of interdisciplinary research activities such as molecular and cellular biology, protein chemistry, proliferation and differentiation signals, regulation of gene expression, membrane biology, etc. Hence this well-referenced book will be most useful to many investigators.

The editors have collected 46 chapters written by different experts and have assembled much basic knowledge to update us on both innate and adaptive (or acquired) immune responsiveness. The innate cellular responses provide the first line of defense against invading microbes. By production of mediators when activated they set the scene for the activation of the adaptive responses with specificity for the challenging antigen(s). Type I interferons are produced very rapidly in many infections; natural killer (NK) cells and their subsets, γ/δ cells, complement components, phagocytes and granulocytes (i.e. macrophages and neutrophils; are of central importance in innate responsiveness by formation of various chemokines and cytokines (interleukins). Pattern recognition receptors (such as Toll-like receptors (TLR)) are expressed by certain cell types. They recognize particular groups of microbes or their components and play a major role in early cell signaling events. Although the innate immune responses do exert some control over the pathogen load early in infection, they are rarely sufficient to totally clear intracellular microbial infections, be they caused by viruses or parasites.

Adaptive immunity depends on a highly complex and intricate network of interactions between different cell types and their subpopulations, regulated by their production of mediators, i.e. cytokines, chemokines, interferons type I and II . The adaptive immune responses are driven to a large extent by antigenic challenge resulting in the clonal expansion, differentiation, and maturation of diverse clones of antigen-specific B cells to form circulating antibodies (humoral immunity) and of antigen-specific cell-mediated responses by thymus-derived T cells. These vary in phenotype, cytokine formation, and effector function. In this brief introduction it is impossible to do justice to all the main players in this amazingly multifaceted system. However, this volume contains detailed articles on the many cell types involved, the lymphocytes and their subpopulations differing in phenotype and function, their lifestyle, and their antigen recognition receptors and patterns.

In addition the main antigen-presenting cells (APC), i.e. dendritic cells and macrophages, are essential to activate B and T cells from their resting and naive state.

The T cells are divided into two major subpopulations according to their phenotype, the expression of the CD4 and CD8 surface markers, as well as their functional differences. Chapters 19 and 21 convey the antigen-processing pathways and the assembly of the major histocompatibility complexes (MHC) with antigen-derived fragments for recognition by the T-cell receptors. $CD4^+$ T cells recognize antigen-derived fragments in conjunction with MHC class II molecules on the cell surface while $CD8^+$ cytotoxic

T cells (CTL) see antigen-derived peptides in association with MHC class I. The MHC gene complex is of course highly polymorphic and the binding of diverse antigen fragments to the polymorphic MHC molecules varies in different haplotypes in the population. Both T and B cells are the source of many cytokines and chemokines when they recognize antigen. Nonantigen-specific B and T cells are also recruited by chemokines into infected or damaged areas, and become activated by bystander cytokines in the environment of lymphoid organs to further enhance inflammation.

Excessive levels of certain immune responses and resulting cytokines can cause serious immunopathology as seen, for example, in certain infections, autoimmune disorders, allergic reactions, or hypersensitivity reactions. Thus it is not sufficient to activate and induce immune responses, but, to prevent lymphoproliferative disorders and overactivation of cells in the lymphoid tissues or infected organs, it is also essential that the immune cells can be down-regulated. Regulatory T cells and their formation of inhibitory cytokines (such as the interleukin (IL)-10 and transforming growth factor (TGF)-β) or apoptotic signals fulfill this need.

Chapters 40–46 are devoted to recent approaches used in efforts to develop new vaccines. There are no effective vaccines as yet against serious health threats caused by some extensively studied and fully characterized pathogens, as well as by newly emerging infectious agents. However, this is an area that still requires intensive research and study. Each infectious microbe is a law unto itself and differs in tissue tropism; it is endowed with different mechanisms to evade immune control, varies in its host–pathogen relationship, lifestyle, and the effects of host genetic influences. Therefore each microbial infection has to be examined as such and there are no obvious shortcuts. Not all immune responses are beneficial and deleterious reactivities have to be avoided. Clearly, there is a need to define appropriate protective responses against intracellular infections. We would like to be left also with immune memory (i.e. antigen-specific lymphoid cells that respond more rapidly and are present at a higher frequency than found in naive hosts) for defense against subsequent challenges with the same microbes. The induction of antibodies alone is not necessarily the answer to all our prayers. Chapter 18 addresses the therapeutic application of monoclonal antibodies.

This *Immunology* volume provides basic information on broad aspects of immunology that must be taken into consideration when dealing with infectious diseases and so many clinical problems and disorders involving lymphoid cells and pathological inflammatory responses. This volume will be invaluable to students and post-doctoral investigators, as well as experts, microbiologists, immunologists, basic or clinical scientists, and clinicians in many fields.

IMMUNOLOGY WITH AN EMPHASIS ON INFECTIOUS DISEASES: A RETROSPECTIVE

The modern science of immunology stemmed from the germ theory of diseases at the end of the nineteenth century and then developed in close connection to it. At that time, immunology was decisively empowered by the early successes of rabies vaccine and anti-diphtheria serotherapy and contributed to establish bacteriology as one of the pillars of modern medicine.

In the twentieth century, immunology acquired a growing autonomy and distanced itself from the domain of infectious diseases. Immunology dealt with a growing number of affections with no infectious agent identified, or even hypothesized. The enlargement of the definition of antigenicity, addressing a whole array of molecules (Landsteiner 1936), helped to emancipate immunology from its historical origins.

Immunology as the 'science of the immune system' acquired connections with other systems in the body such as the endocrine or the nervous apparatus. The immune system played a major role in the selection of species and individuals and the present ontogeny reflected these developments. Immunology, the 'latest language of medicine' as tentatively named (Moulin 1991), could claim to be becoming the science of the 'system of systems', because the immune system was increasingly shown interacting with other vital functions and regulating them.

The dream of the eradication of microbes was nurtured by the success over smallpox and infectious diseases, and the observation of the world's spectacular demographic expansion. Yet, in the immunology of the last quarter of the twentieth century, the share of research linked to infectious diseases declined. Some scientists, focusing on idiotypic–anti-idiotypic relations, went so far as to discard the primacy of infections in the understanding of immune responses, and set forth the distinction between a so-called peripheral system dealing with external pathogens, corresponding more or less to the infection-oriented immunological tradition, and a central part, or immunological core, described as a self-centered network (Coutinho et al. 1984).

These last years have been marked by a revived interest in infectious diseases. In sharp contrast with the previous period, the last decade of the twentieth century has witnessed a growing anxiety over the so-called return of infectious diseases, and disenchantment over the perspectives of a rapid and complete eradication. The fight against ancient and new plagues has been resumed with accrued vigor and traditional tools have been refurbished with the help of all-powerful molecular biology.

Inflammation, an antiquated concept taking us back to Celsius and Roman times, is again finding a central

place in immunology. Inflammation associated to infection is a crossroad phenomenon that includes secretion of multiple factors. A whole network of molecules, entertaining complex relationships with each other, thus contributes to the permanent homeostatic control of the body and adjustment essential to life (Canguilhem 1966).

The immunology of infectious diseases has been rehabilitated in a new guise, most notably expressed in a molecular language. Immunology, once described as a science attached to the ideal of specificity, or the 'science of boundaries' trespassed only in rare cases (Moulin 1997), is by now deeply concerned with the exchange of biological material across the species barrier. The trends of innate and acquired immunity, dubbed natural and adaptive immunity, go intertwined through recent immunological literature, opening a flow of speculations over evolution, selection, and survival.

THE 'RETURN' OF INFECTIOUS DISEASES

With the development of microbiology at the end of the nineteenth century, the initiative seemed to be in the medical camp for ever, and a definitive advantage given to the doctors' side. The isolation and cultivation of germs made plausible the hope of destroying them.

The eradication goal was immediately perceived as at hand not only by journalists but also by scientists (Gradman 2000). Louis Pasteur set the tone by predicting the demise of tuberculosis, rabies, plague, and cholera. Although Pasteur admitted that new plagues were to come, he was confident that, as they would show up, fresh science would take over. This fighting adopted almost mystical tones. Scientists crusaded to relieve humankind from the original sin lurking in the body in the guise of germs. Not that the physicians of the past had ignored any ontology of disease. On the contrary, they had all the time been familiar with the general idea of the 'seeds of the disease' (Nutton 1983). But so long as this theory was of little practical value for curing patients, this had been a mere speculative luxury.

Operating in the wake of World War II, the World Health Organization (WHO) decided to give a decisive impulse to the eradication of infectious diseases. Its officers launched the campaign against smallpox which led to the announcement of its eradication in 1979 and provided the model, to be followed by tuberculosis, malaria, poliomyelitis, and other diseases.

Although immunology provided a whole line of vaccines, antibiotics, by alleviating the burden of infections, reduced the pressure on immunologists to explore the inadequacies of the immune response. Immunologists interacted more closely with biological research in embryology, neurology, cognitive sciences, cancer studies, and pharmacology, and provided tools and concepts to other disciplines.

Between the 1980s and the present time, the period under scrutiny in this chapter, immunology faced events that boosted and remodeled its activity in the domain of infections.

Today, in Africa and Asia, countries still bear an enormous infectious burden and AIDS has shortened by many years the gain in life expectancy, which immunization and modern medicine had helped to procure. In contrast, in industrialized countries, less than 10 percent of mortality is attributed to infectious diseases, and even AIDS has only globally induced a rise of about 1 percent. Yet, infectious diseases have stepped again to the forefront for many reasons:

- As a result of the neglect of immunization and political unrest, some ancient plagues have burst out again in Africa. Yellow fever erupted in Brazil, in urban settings, in 1998. A threat weighs over Asia, historically free from yellow fever without demonstrable immunity to it, in spite of the presence of other flaviviruses. Hemorrhagic dengue is now expanding in South America and the Caribbean.
- The microbial world has displayed a previously unheard of diversity, including new classes of pathogens, among which bacteria such as legionellae, viruses such as the bunyaviruses, the parvoviruses, the arenaviruses to which belong the viruses of hemorrhagic fevers (Machupo, Junin, Lassa, Sabia), the filoviruses (Ebola, Marburg), and above all the retroviruses.

Systematic investigation in birds and rodents around the world has detected thousands of viruses that have no ascertained pathogenic role. Field studies represent at best a glimpse into the diversity of viruses circulating among rodents, vectors, and mammals – a potential reservoir of pests for the rest of the living world.

Defying the dogmas of molecular biology, unconventional particles of poorly defined status, such as prion proteins, have been involved in the genesis of neurological disorders (Gajdusek 1977). With the demonstration of the transmissibility of the bovine encephalitis to humans, natural order was challenged, because the species barrier is no longer an absolute protection. Inasmuch as the tomato spotted wild virus, a bunyavirus akin to the Rift Valley fever virus, is adapted to plants, plant viruses could grow on vertebrate cells.

Laboratories and hospitals are no longer sanctuaries. Hospitals, considered once as hotbeds of infection, a threat to neighborhoods, reappear as dangerous places. Nosocomial infections are scaled up to 10 percent of the registered infections, even in Africa, although with germs differing from those in the West. It is in a hospital, in 1976, that the Ebola epidemic burst out, as well as a few months later, in Yambuku in Zaire, and in 1995 again in Zaire.

In the laboratories of the industrialized world, accidents may happen. The Marburg virus, close to the Ebola virus, draws its name from the city where it made its way from monkey cells used for vaccine production

in 1967. Until recently, there have been reported cases of infected people among the staff handling the Rift Valley fever virus, identified in 1983 and extremely contagious. The creation of high security laboratories (P4) illustrates the difficulty of manipulating ultra-virulent and unidentified infectious material. But there are no P4 laboratories close to the infection foci in Africa. Moreover, growing resistance of microbes to antibiotics instilled the idea that no defense line would soon remain available. In a pre-vision of this therapeutic collapse, the mechanisms of immunity should be revisited, and immunologically inspired treatments investigated more carefully.

The return of infectious diseases, at the beginning of the new millennium, has roused an anxiety aggravated by the recent threat of bacteriological warfare. Mass media currently discuss germ pulverization in the atmosphere; they evoke the mad scientist working for terrorists, flooding germs and toxins in water pipes, inventing genetically modified microorganisms, resuscitating the smallpox virus in populations deprived of immunity.

The 'Conquest of Diseases' (Winslow 1943) has been replaced by the idea of a 'victory à la Pyrrhus' (Ameisen 1999, p. 158), with nobody vanquishing or being vanquished. Epiloguing on this 'return', which typically reveals postmodern distress in a 'global' world, we have to admit that the notion of 'new virus' actually reflects our previous ignorance and witnesses the extension of our inventory of the living world. It is as much the vanishing of an illusion, thanks to the improvement of our detection tools, as the awareness of a grim reality. It is not only the immune system that has been taken off guard; many systems of surveillance in the world have been dismantled, in the former Soviet Union, for example, or in Africa.

This so-called return, be it the emergence of radically new plagues, or the re-emergence of previously tamed epidemics, confronts long-term germ evolution with the quickening step of human history (Moulin 1996b). The relationship between humans and the environment has been transformed, some say perverted, by human activity, and a debate bears on the necessity of rethinking a new alliance or even a 'new contract' (Serres 1990) between 'Man' and 'Nature', which he possesses far less than he is possessed by it.

The AIDS epidemics has provided an unmatched opportunity for dissecting the immune mechanisms. The virus, when dormant in the cells of the immune system, is relatively unobnoxious for most human tissues, with perhaps an exception for the nervous system, but it is deleterious to the immune system and transforms the body into a 'city without walls' (Epicurus) ready for 'opportunistic' attacks. Our present pessimism is rooted in our failure to produce a vaccine rapidly, in spite of the unprecedented research effort. We still miss a satisfactory animal model and an anchorage in the natural history of the disease, documenting spontaneous cure. Virus lines developed in the laboratory swiftly behave like 'circus strains', to use a phrase coined by French biologist Charles Nicolle, too obedient to the dompter's whistles and falling rapidly apart from wild viruses. After the introduction of active tritherapy, much is expected from the manipulation of the immune system, giving it a chance to take over when specific therapy is discontinued.

THE NEW AGE OF INFECTION AND IMMUNITY

The development of monoclonal antibody technique has followed a paper published by Cesar Milstein and Georges Köhler in 1975 in *Nature* and crowned by the Nobel prize. This technique, initially conceived by Milstein to explore the immunoglobulin genes and the diversity of antibody formation, turned out to be available for all kinds of studies. Hybridoma technology (the name appeared 2 years later) has resulted in immortal cell lines producing, at will, any human or murine antibody of chosen specificity, a wonderful tool for genetics and immunogenetics. The T4 count (CD4 cells still rank among the major indicators of the risk for opportunistic infections) was defined with the help of monoclonal antibodies (Cambrosio and Keating 1995). Flux cytometry uses monoclonal antibodies to mark cells and the cell sorter has turned into a quantitating machine (Cambrosio and Keating 1994). Novel ligands for cell-surface molecules can be identified using high-avidity recombinant reagents displayed on fluorescent beads. These reagents allow description of interactions between cells and molecular analogs of receptors or targets (Wedderburn and Dianda 2000).

Genetics had at first been little concerned with infectious diseases, being absorbed in the model of 'innate errors of metabolism' (Garrod 1909) and research on diseases recognized for a long time as being hereditary, based on family pedigrees and aiming at genetic counseling. Innovations included karyotyping techniques and the selection of new animal models that mimic human pathologies. Standard mice were produced between the two world wars by the Jackson Laboratory, established by the geneticist Little (Löwy and Gaudillière 1998). The center has become the world leader in the study and production of inbred, genetically homologous strains of mice.

'Knock-out' (KO), with artificially defective genomes, have provided exquisite tools for the analysis of the immune system (Mak et al. 2001). Studies have shown that the immune system finds a new balance when it loses some component. The deletion of a gene coding for an important molecule of immunity may have consequences in a remote sector of physiological life, e.g. mice missing the *PrP* gene, which are insensitive to prion infection, display anomalies in systems other than the immune system. But genetic manipulations do not

necessarily result in gross alterations in development and survival. The block that occurs to some pathways through genetic defects does not necessarily compromise the formation of innate or even acquired immunity, suggesting flexibility and redundancy as major features of the immune system, which is critical for survival.

In the two last decades, the actors of the immune system, studied with new tools, have multiplied. The immunological band once cartooned by Gershon in the 1970s has by now expanded to the dimensions of a symphonic orchestra (Gershon 1980).

In the mouse, two functionally different CD4 populations were described in 1989: T-helper 1 (Th1) and T-helper 2 (Th2) (Mosmann and Coffmann 1989). The T-/B-cell dichotomy, corresponding more or less to the historical split between the cellular and humoral response, has mirrored itself in a new subdivision in the T-cell population between Th1 and Th2 subsets, key tuned to different classes of pathogens, extra- and intracellular. Characteristically, this division was based on different patterns of lymphocyte secretions. The observation was soon extended to the human case (Romagnani 1996).

Another new subset of cells has been dendritic cells. When they were described by Paul Langerhans in the dermis (Langerhans 1868), they had nothing to do with immunity. Langerhans called them dendritic because of their aspect, which was reminiscent of nerve cells, and hypothesized that they belonged to the nervous system. The French dermatologist Darier later noticed their frequency in inflammatory lesions (Darier 1900). Dendritic cells are scattered throughout the body, close to the main portals of microbe entry. Although the phenomenon called crosspriming or crosspresentation was described in 1976 (Bevan Cross 1976), their role was diversely interpreted before being viewed as essential to the onset and modulation of the immune response. In lymph nodes, they are sufficiently 'professionalized' (Amigorena 1999, p. 932) to instruct naïve lymphocytes and present antigens from infected cells, in association with class I molecules, to T-cytotoxic lymphocytes. In AIDS, they are among the first cells to capture the virus in contaminated fluids. This strategic position makes them appear as good targets for potential vaccines at an early stage of primoinfection.

Dendritic cells identify pathogen agents via toll-like receptors, so called because of an analogy with proteic receptors in *Drosophila*, which are mediators of embryogenesis. Toll receptors recognize molecular patterns shared by numerous pathogens of the gram-negative families (Rock et al. 1998). The activation of these receptors in mammals leads to the production of antimicrobial peptides such as cecropin and defensin.

The genetic diversity of B lymphocytes results primarily from the recombination of the many genes harvested in our body libraries. To build the receptors that display specific targets on their shields, lymphocytes make use of enzymes under the dependence of two genes called recombinant-activating genes (RAG). These genes, shared by all species endowed with T lymphocytes such as mammals, birds, and some fish, probably derive from a very primitive microorganism, a transposon, that was integrated into the human genome millions of years ago.

In 'the golden age of genetics and the dark age of infectious diseases' (Tibayrenc 2001), how did immunology evolve? The biologist Paul Ewald sharply subtitled his popular book *Plague Time* (Ewald 2002) *The new germ theory of disease*. Post-modern immunology features:

- a new definition of pathogens and pathogenicity
- a focus on infection currently redefined
- a genetic agenda for the assessment of the germ/host relationship.

The nature of the pathogen has diversified. RNA viruses are particularly proteiform, because they mutate rapidly when they multiply in the host cells and because their polymerase, an enzyme essential in the synthesis of nucleic acids, does not entail any mechanism for repairing errors. RNA viruses, numerous in plants and animals, are good candidates for the etiology of many chronic affections such as multiple sclerosis or Parkinson's disease.

Genetic recombinations frequently happen between two subpopulations of one microbial species, in a vector or a host, with unpredictable consequences for pathogenicity.

The nature of pathogens has become elusive. It is not excluded that viroides, small monocatenary pieces of RNA involved in transmissible diseases in plants, play a role in humans and animals. In the cerebral tissue of patients suffering from Creutzfeldt–Jakob dementia, the PrP protein results from the alteration of a normal protein. Although the modalities of infection by prions remain far from understood in their entirety, the infectious role of proteins is now well established.

Some pathogens had been known about for a long time in the animal kingdom, but damaged immunity in humans (whatever the cause, and they are many in the modern world, such as chemotherapy, transplantation, severe congenital defects) procures them new opportunities. These 'opportunist infections' are best illustrated in the case of microsporidia.

Microsporidia are unicellular parasites that are widespread in the animal kingdom. The German zoologist Naegeli described corpuscles, which he called *Noema bombyci*, under the skin of the silkworms in rearings. Babiani suggested, in 1882, the name microsporidia because of their tiny dimensions. Their position in taxonomy is still controversial. The absence of mitochondria favors a 'regressive evolution', with loss of important organelles. With the help of the high-resolution electronic microscope, it became possible to

investigate the pathogenic power of this supposedly benign parasite. The first human case described was in a patient stricken with AIDS (Desportes et al. 1985). The story of this patient, whom the author came to know personally, was most unfortunate because for a long time there was a failure to attribute the disease correctly to a transfusion in Haiti. Many cases have been reported since in AIDS and immunosuppressed patients. In athymic or severe combined immunodeficient (SCID) mice, parasites invade the whole organism and infections of microsporidia are lethal.

The very notion of infection has lost its clear outlook (Evans 1993). Medical interest has moved from canonical descriptions of infections, almost in Hippocratic format, to the search for all possible symptoms. Computer technology has played a crucial role in this shift from clinical to bibliographic knowledge. Primoinfection linked to a given pathogen is shown to generate a broad spectrum of situations, from the healthy carrier to acute and severe forms, and to chronic diseases pursuing their course in the absence of a detectable pathogen. Murine models, in the case of leishmania infections, for example, illustrate the clinical diversity of human forms, from the benign oriental sore to deadly kala-azar.

The opposition between infection and hereditary disease is no longer clear cut. The transmissible spongiform encephalitis such as that of Creutzfeldt–Jakob disease exists under two forms: the infectious one, including cases that result from treatment using growth hormone extracted from patients who died with dementia, and the hereditary one.

Since the late 1980s, the role of chronic infections as facilitators of more severe diseases has been discussed: they would weaken the immune system by overstraining or overstimulating its capacity to respond. In 1989, in order to explain HIV diffusion, Luc Montagnier suggested such a role for mycoplasma infections. Later, sexually transmitted diseases associated with *Chlamydia* have been incriminated. The general idea of an infection ecosystem in unstable equilibrium in populations, or 'pathocenosis', as put forward by the late historian Mirko Grmek (1969), has led to the global incrimination of chain reactions in the immune system without assigning the first signal.

New immunology addresses the question why an epidemic intervenes in the course of the silent co-evolution of germs and their potential hosts. Closer articulation of the innate response, allegedly more primitive, and the adaptive response, claimed to be the privilege of the most recent species, has reinforced the link between our sophisticated organisms and the rest of the living world, and restored a more balanced view of the respective advantages and disadvantages among species. Already sobered by moral considerations on the cyclic return of the 'brute beast' in humans (Nicolle 1933), our positivist optimism has been dampened by the discovery of the highly innovative capacity of germs and their ability to exploit molecular niches in the intimacy of the body.

To address these challenges, immunology operates within the framework of the selective theory (Silverstein 1989), which still prevails, even though it has lost its original simplicity since Burnet offered the idea that the antigen selects the corresponding clone, which subsequently expands T cells to identify the molecules of the self carried by the histocompatibility complex on antigen-presenting cells. As far as immunity is concerned, the differences in repertoires between individuals account for both the havoc caused by epidemics and the survival of a few. Differences between high and low responders were suggested by Ludwig Hirschfeld in his seminal book, *Konstitutionserologie* (Hirschfeld 1928). Biological individuality is considered alternately as an obstacle to general strategies of immunization, leading some authors to recommend immunization 'à la carte', and as a providential reservoir of biodiversity, illustrating the leibnizian principle of 'multiple splendor' in 'Creation' (Moulin 2001) and the maximization of good.

The history of primoinfection is one of mounting a powerful immune response that involves all known components of immunity, from the old crones, antibodies and cells, to the creatures of novel immunology, cytotoxic cells, Th1 and Th2, from Metchnikoff's phagocytes to dendritic cellules and natural killers, from Jules Bordet's complement to cytokines and lymphokines.

Today, knowledge about HIV infections illustrates the general development of such knowledge about the immune system, the vulnerability of which was thus exposed. The way HIV infection proceeds fatally toward a chronic form by escape from the immune system is extreme and cannot constitute the general model of all kinds of primoinfection. Yet it has reshaped our understanding of the encounter between germs and organisms that may shelter them.

Transmission of germs and genes, now more integrated than in the past, constitutes a general and unifying perspective. A century and half after the beginning of bacteriology, there is space for multicausal explication. With the emergence of notions such as genetic pattern or pathogenicity islets in the genome, which mean more than constitution, terrain, soil, natural immunity, predisposition, etc., immunogenic knowledge and epidemiological data point to the inequality of bodies, without denying the role played by lifestyle.

THE MOLECULARIZATION OF IMMUNOLOGY

Immunology has entered the modern era by exploring the genetic aspects of the immune response and by adopting molecularization. Molecular immunology is convenient shorthand for the study of the molecules of

the immunological orchestra and their interactions (Moulin and Silverstein 1990), with the tools of molecular biology. This abbreviation refers to both an ideal and an enterprise in the making.

The molecularization of immunology raises the question of the changing position of immunology among other biological disciplines. Did it significantly help it to solve physiological issues and open new diagnostic and therapeutic vistas in diseases (Panem 1984)? In the 1980s, cancer was the main target of the 'immunological revolution' (Fridman 2000): molecularized immunology was expected to open a 'fourth line' of therapies, after radiotherapy, chemotherapy, and surgery (Löwy 1997). In the 1990s, infectious diseases were reconsidered as possible beneficiaries of advances in the field, from a curative and also a preventive viewpoint (vaccines).

The breaking of the genetic code and the identification of the nucleic acids as the support of heredity have been presented as *The Eighth Day of Creation* (Judson 1979). But it was only the beginning of an era that saw biologists manipulating gene segments and expressing them in vectors. The colossal enterprise of the Human Genome Project, in contrast to the medical programs for eradicating diseases, has been regularly ahead of its deadlines. Mapping the human genome has become the totem of the new molecular biology, in a planetary vision (Jordan 1995).

If the development of restriction enzymes from the 1975s onwards marked an important milestone of molecular genetics, the 1975 hybridoma paper by Köhler and Milstein (1975), ending with a few lines on the applications for the production of antibodies of medical interest, is considered as a similarly crucial step in the molecularization of immunology, in terms of phenomenological analysis, and production of tools and therapies. Either ancillary to molecular biology or bringing its own recipes, immunology has come into the scientific mainstream. Immunologists can pursue the historical mission that its pioneers had assigned themselves. The goal of specificity, a major tenet of early immunology (Mazumdar 1995), is alleged to be reached thanks to elegant techniques allowing the dissection of the immune response into all its components and the identification of all relevant pathways. Since the 1980s, molecular biology has allowed the localization of genes for capsules, toxins, adherence factors, invasion and survival cell factors on plasmids, bacteriophages, and even on chromosomes, leading to a description of 'pathogenicity islets' and the identification of a whole array of molecules involved in infection and immunity.

Interferons were first described by Isaacs and Lindenmann in 1957, referring to the phenomenon of viral interference. They were used as antitumoral agents only some 30 years later. They are today considered as both constitutive and induced immunity factors.

David (1966) and Bloom and Bennett (1966), independently hypothesized that a substance, formed by lymphoid cell–antigen interaction, inhibits macrophage migration. Bloom called this factor migration inhibiting factor (MIF). In 1969, Dumonde et al. suggested the term 'lymphokines' for substances different from classic antibodies, generated by antigen-activated lymphocytes.

In 1975, while investigating a viral etiology of leukemia in Gallo's laboratory, Morgan and Ruscetti noted that media from phytohemagglutinin (PHA)-stimulated lymphocytes were capable of prolonging the growth of cells from leukemic cells in continuous cultures. The new molecule (called T-cell growth factor (TCGF)), and not the antigen, allowed cultured normal lymphocytes to maintain their functions. In 1978, a murine cytotoxic cell line was used as a bioassay for testing this lymphokine. An assembly of immunologists recognized the identity of thymocyte mitogenic factor, killed helper factor, and lymphocyte mitogenic factor, which have previously been described, and co-chromatograph with TCGF. The subsequent cloning and purification of interleukin (IL) 2 by Taniguchi et al. in 1983 confirmed that all these activities were ascribed to a single molecule. IL-2 is presently one of the best-known molecules. B-cell-stimulating lymphokines, such as IL-4, IL-5 (also active on eosinophils), and IL-6, were successively defined. Human lymphokines were thought to be similar to their mouse homologs, although most experiments needed to prove it were impossible for obvious ethical reasons.

The availability of a variety of hemopoietic growth factors has allowed the development of in vitro approaches to the differentiation of hemopoietic lineages. These factors regulate genes that are required for the maintenance of viability during proliferation and differentiation. With the advances in modern biotechnology, many of them have become available in sufficient amounts and purity to study their effects in vitro and in vivo. It was expected that knowledge gained from these studies would lead to new approaches to the treatment of human disease.

As more factors were identified and cloned, the complexity of their effects and interactions was perceived. 'Cytokines', immunologically active proteins that bind to specific receptors on target cells, can be produced by a wide variety of cells, e.g. IL-1, stimulated by lipopolysaccharide (LPS) and a component of Gram-negative bacteria, is secreted by monocytes; many other cells can, however, make IL-1. Among many bacterial products, the ubiquitous LPS (Besredka 1906) has been characterized as a potent stimulus of both immunity and inflammation (Cavaillon and Le Garrec 1998).

As growth factors, cytokines have been particularly useful for facilitating the culture of cells reputed to be difficult to grow in vitro. With further recognition of the numerous cell subsets involved in immunity, additional ingredients were poured into the 'cauldron'. How these molecules are classified has currently depended on whether an endocrinologist, immunologist, or hematolo-

gist described them first. Later, their protean properties have somewhat bewildered researchers, who are always eager to advertise them as potential immunostimulants or more generally immunomodulators, but embarrassed for classifying them and putting them into a hierarchy. The availability of purified recombinant factors, the development of radioligand assays, and the production of monoclonal antibodies to surface determinants have permitted quantitative study of the chemistry of ligand–receptor interactions. The information contained within the structure of the factor is received by the receptor and rapidly translated into a limited repertoire of chemical internal signals that affect cellular functions.

Cytokines characteristically act at a site distant from the cells that produce them, witnessing the potential of the immune response to reach target organs far from the microbial entry. However, a regulation is required to provide balances and checks of cytokine production. Cytokines are now viewed as the key to the understanding of the inflammatory reaction and the regulation of the immune response. Anti-inflammatory cytokines, such as the 'quintet' of IL-4, IL-10, IL-13, interferon-α and the transforming growth factor (TGF) would have the capacity to repress proinflammatory cytokines elaborated by activated macrophages.

Chemokines, described in 1992, are a family of small proteins that recruit circulating cells and play an important role during inflammatory reactions. Their function is chemotaxis or attraction exerted on cells. Chemokines play also a role in angiogenesis, collagen production, and proliferation of hemopoietic cells. This family includes numerous members, among which is IL-8, and has raised a considerable interest, because of its potential therapeutic action in AIDS.

In contrast to the ideal of narrow specificity, the system is redundant. Chemokines are promiscuous in receptor usage – several cells produce several chemokines with an overlapping sector of action. The robustness of biochemical pathways renders their output relatively insensitive to change. The natural polymorphism occurring in an outbred cell population does not usually affect the immune response for this reason. No chemokine is uniquely active on one leukocyte, and usually a given leukocyte population has receptors for and responds to different molecules. Most known receptors interact with multiple ligands, and most ligands interact with more than one receptor.

Generally speaking, it is impossible to discriminate between 'good' and 'evil' cells and molecules. Infection is a drama with successive steps where immediate destruction of viruses by specific cytotoxic cells may be associated with negative indirect effects on non-infected cells. Antigen–antibody complexes can protect viruses hidden in lymph nodes. Although chemokines can stick to ligands, preventing infection of the cells by viruses, cytokines can diminish the regeneration of cell lines, and trigger destruction in neighboring cells.

The molecular biologist Jean-Pierre Changeux has characterized the immune system as an allosteric orchestra, to emphasize the role of allostery or alternate changes in chemical structure, which induces functional diversity, as illustrated by hemoglobin in the Wyman–Changeux–Monod model. Shared signals, structural analogies in receptors forming families that overlap the species barrier, manifest the unity of the molecular language in which infection and immunity are described today.

AN EMPIRICAL VIEW OF THE IMMUNE SYSTEM

In 1990, the author wrote, with Silverstein in a book dedicated to 'The role of cells and cytokines in immunity and inflammation, that ''the past decade has been marked more by technologic than by conceptual developments''' (Moulin and Silverstein 1990, p. 3).

A tentative model of disease has been based on dysfunctional production of and responsiveness to cytokines. The administration of LPS reproduces some of the disease events by inducing an outburst of cytokines. Coordinated reactions, facing danger, involve a reorganization of self-perception and behavior. Anorexia, sleepiness and drowsiness bordering on comatose states, onirism, and retreating from the world had been described for a long time by patients themselves. Infectious disease has been one of the most studied human behaviors. A masterpiece of Elizabethan literature in the Renaissance is John Donne's *Reflections upon Emergent Occasions*. Donne wrote, during a typhus epidemic, his detailed personal account of the events accompanying disease, fever, and delirium, and the effects of consulting the physician and the priest.

The cold/hot opposition was among the basic tenets of the humoral theory that for centuries shaped medical thinking. Fever has remained the clinical hallmark of inflammation, and is narrowly associated with disease, trauma, or infection. The physiology of fever is better understood in the context of recent immunology: cytokines are responsible for fever induction and the behavioral changes during the acute phase of infection.

In response to a stimulus such as LPS, the body's thermostatic control center within the hypothalamus increases its set-point temperature. The body then increases its core temperature to match the new level. Physiological (vasoconstriction, reduced sweating) and also behavioral modifications (drinking warm liquids, putting on warmer clothes) drive up the body's temperature. When the fever breaks, the body temperature again is too high relative to the new set-point, and physiological and behavioral modifications result in a lowering of core temperature, increased blood flow in the skin, sweating, and the desire to drink cold liquids. Fever is a central episode of immunity and infection. Clinical considerations on the onset and rhythm of fever

paroxysms remain a decisive component of the biomedical enterprise in the era of the cytokine orchestra.

At the onset of the disease, inflammation is a nonspecific restorative response of tissues to soluble chemical mediators produced after injury. If the harmful agent is not removed or the disequilibrium persists, a pathological state of chronic inflammation ensues. If the inflammatory cycle is broken, the host is restored to its preinflammatory state of physiological equilibrium, but, as the French philosopher of medicine Georges Canguilhem stated in many of his writings, there is no return to cellular innocence.

IN SEARCH OF A MECHANISM UNIFYING IMMUNOLOGY

The tantalizing identification of multiple factors in constant interaction has resulted in a 'balkanization' of research, i.e. division of research into small separate sections. It has blurred the primitive simplicity of the immune response with its two arms – the informative and the effective – once gracefully linked in a kind of reflexive arc.

The distinction between self and nonself is still very much there, even if many doubts are expressed about its pertinence. Frank Mcfarlane Burnet had long ago envisioned the possibility of accounting for the nature of the self in precise molecular terms, before retreating to use of the phrase in a metaphorical sense. Zinkernagel and Doherty's (1979) demonstration that the T-lymphocyte receptor reacts with a polypeptide attached to a major histocompatibility complex (MHC) molecule reinforced the notion of the recognition of nonself in the context of self. At the onset of molecular immunology, there were attempts to describe more precisely the self as the 'peptidic self' (Kourilsky and Claverie 1988).

Generally speaking, however, the self/nonself distinction functions more as a general background than as an effective theoretical construct (Moulin 1994), an indication that, although many questions remain to be clarified, most immunological reactivity is oriented for the sake of survival of the organism. It does not radically differ from expressions such as 'genes' or 'immunity', the meaning of which is constantly fluctuating. Although it has been said that 'The self is constantly defined anew, which is another way of saying it doesn't really exist at all' (Richardson 1996), the reference to self and nonself ensures communication between generations of scientists and between scientists and their public.

The last few decades have seen an outburst of data where it is difficult to single out unambiguous signals. Epistemologists insist on the dependence of scientists, more than theory, on the experimental systems that they handle on a daily basis (Rheinberger 1997). It had been suggested for a long time that tolerance can be induced by small as well as overwhelming doses of antigen, but never has it been made clearer that the self/nonself distinction is made empirically, case by case, and the meaning of immunological phenomena is practically determined. For Zinkernagel (2000), there is nothing absolute: immunity is, in his own words, a matter of dose, space, and time. Philippe Kourilsky (1998), inaugurating the first chair of 'molecular immunology' in France in 1998, stated the same idea:

> Specificity in the immune system, more than on the complementarity of structures, is founded on the dynamic of cellular activations: some defence mechanisms are deprived of specificity and acquire it only by operating at the right time, at the right place.

This perspective is not as empirical as it appears at first sight. It simply moves the emphasis to the importance of microenvironment and local determinism. Cells and factors are not identical because, following a 'leibnizian' doctrine of individuality, they are always located in space and time. Obviously, we miss an all-encompassing and simultaneous view of all compatible phenomena in the realm of immunity – the vision of GOD (for Generator Of Diversity), to recall Melvin Cohn's jocular and unmistakably serious address. Any activation can result in overreaction and destruction of antigen-stimulated cells. The recognition of autoreactivity as a physiological phenomenon resulting in autoimmunity has illustrated this empirical turn.

The identification of autoreactive cells within the lymphocyte repertoire recalls the interpretation of these cells playing a role in body homeostasis, such as immunocircuits controlling the antibody level, e.g. through idiotypic interactions. Autoimmunity became pathogenic only when effector cells penetrated organs, favored by microchanges in the environment.

It is currently being suggested (and has been suggested for decades) that infections may cause autoimmune diseases. The molecular basis still remains to be established in many cases, but it is a fascinating hypothesis, also available for many idiopathic diseases. The scenario would be the following: molecular mimicry between a pathogen-derived antigen and a host antigen would set off subliminal autoimmunity.

T-cell receptor recognition of antigen looks highly degenerate. In experimental models, myelin basic protein, involved in multiple sclerosis, may display similarities with peptides presented by MHC structures. Mimicry of human sphingolipids by lipopolysaccharides from *Haemophilus influenzae* may provoke the Guillain–Barré syndrome or Lewis-like polysaccharide antigens from *Helicobacter pylori* lead to atrophic gastritis in humans. The analogy can go beyond primary amino acid sequence homology and includes shapes in space (e.g. between arrangements of a three-domain coil of HIV-1 glycoproteins and contact areas of IL-2 with the α, β, and γ chains of the IL-2 receptor), considerably extending the possibilities of chain reactions, even if one

does not know to what extent in vitro studies can be extrapolated to autoimmunity in humans: 'Molecular mimicry is round every corner' (Regner and Lambert 2001, p. 185). The production of proinflammatory cytokines would play a decisive role. A genetic component might determine susceptibility to autoimmune diseases, and environmental factors play a role. Everything is possible if the worst does not necessarily happen. In the empirical frame of mind presented above, it has been suggested that autoimmunity can benefit self-maintenance and even be 'a cause of health' (Schwartz and Cohen 2000).

As autoimmune diseases involve stimulation against certain antigens in the individual, no wonder some concerns have arisen about the flirtation with infection called immunization or vaccination, which might also contribute to an autoimmune effect (Shoenfeld and Aron-Maor 2000). Vaccination does not differ substantially from casual immunization through infection, in that it stimulates various pathways depending on both the antigen and the host, and irreversible disorder may be created. The examples of hepatitis B and multiple sclerosis have recently been scrutinized, and the impact of immunization programs on the repertoire of the immune responses in populations taken seriously. The multiplication of vaccines has raised the iconoclastic question of whether they still offer the best strategy for preventing infections. Unfortunately, most of the time, autoimmune diseases have over the last few years been associated with immunization based almost exclusively on case reports – the weakest of scientific evidence.

Although immunization remains a major tool in the management of public health, the consideration of individual reactions, in conformity with the principle of precaution, is forcibly discussed in industrialized countries, where there is a move in favor of immunization 'à la carte'. These considerations reflect the individual and liberal mood of the last few years, with uncertainty about the consequences of this change, at economic, symbolic, or demographic levels.

In the sound and fury of molecular signaling, immunology remains in search of an innovative theoretical framework that would shelter its empirical work and substantiate its claims for solving medical problems and offering clues to general physiology, beyond the sole study of infectious diseases. Not satisfied with the elusiveness of the self/nonself topic, some immunologists have searched for phenomena that convey a general physiological meaning. These attempts have generated much interest and debate and also some confusion; if they stimulated imagination, they fell short of revolutionizing immunology.

The 'danger theory' brought forth by Polly Matzinger has been a flamboyant and significant episode of this quest for a new unifying trend. Matzinger considers that her 'danger theory' has undermined Burnet's classic view of self/nonself discrimination and the paradigm of clonal selection that ruled immunology for more than 30 years. She suggests that, in place of being sensitive to the discrimination between self and nonself, the immune system is in a state of permanent alarm, detecting cellular lesions, which she labels 'danger', after various events, ranging from exposure to tetanus toxin, to a pollutant interfering with the environment, and consequently reacting. In the nineteenth century, physiologists included, in the definition of inflammation, besides Celsius' triad of 'rubor–dolor–edema' (redness, pain, swollenness), '*functio laesa*' or impaired function. Matzinger aimed to discard teleological explanations and introduce simple mechanisms to account for accumulated data in cellular and molecular immunology. The use of the danger notion remains, however, as contextual and teleological as the self/nonself distinction and, even if it clashes with the almost excessive mystique of the self (Silverstein 1997), it does not induce any revolutionary changes in immunologists' theoretical thinking.

The emphasis on apoptosis has also played a role in bringing together different axes of research. The formation of small fragmented bodies, which contain remnants of nuclei, has been documented for a long time in scattered single cells. They were described for the first time in the liver in yellow fever as 'Councilman's bodies'. The Greek word *apoptosis*, used to describe the dropping of petals from flowers or leaves from the trees in autumn, was applied in 1972 by Kerr and collaborators to controlled cell deletion (Kerr et al. 1972) – a genetically programmed cell death, recognized as a vital biological phenomenon. The structural changes would comprise the formation of apoptotic bodies, and their subsequent degradation and phagocytosis.

Apoptosis appears to play an opposite, but also complementary, role to mitosis in the regulation of cell populations. It is determined by intrinsic clocks that are specific to the cell type involved, and plays an important role in the regulation of cell numbers in a variety of tissues under both physiological and pathological conditions. In 1991, Clem and Fechheimer described, in baculovirus (an insect virus), two proteins that inhibit molecules triggering cellular death. One of them at least would belong to a large molecular family operating throughout species. Most viruses such as the human papilloma virus, responsible in the long term for the occurrence of genital cancers, interfere with gene reparation and apoptosis. Anti-infectious defense, aging, and carcinogenesis seem so closely interrelated that any therapeutic or even preventive strategy is at risk of provoking undesired effects.

Apoptosis bears some analogies with Pasteur's hypothesis of 1882 that bacteria invading the organisms rapidly run short of food, a scorched earth tactic on the part of the organism. This theory was rapidly discarded and replaced by a more positive theory focusing on Metchnikoff's phagocytosis. Cell suicide triggered during primoinfection comes very close to the

idea of a mechanism that allows the pathogen to starve to death.

Apoptosis has been put in sharp focus by contemporary studies of the immune system. Immortalized cells may transform into cancer cells and give birth to lymphomas, if the immune system is weakened or strained. Apoptosis offers a clue to the mechanisms that determine whether the immune response will be positive or negative, activation or tolerance. In 1995, Douglas and Thomas Ferguson offered two mirroring images of apoptosis: in sanctuaries such as the eye and brain or the pregnant woman's womb, the cells of the immune system are forced to commit suicide, whereas, in the immune system, it is the infected cells that are forced to commit suicide (Green 1998).

Apoptosis captured the imagination in the scientific race for new ideas. *La Sculpture du Vivant* by Jean-Claude Ameisen, dedicated to apoptosis in immunology, refers to an episode of Odyssey on Ulysses in the Messina Straits (Ulysses attached to the mast in the ship listens to the mermaids' songs and wants to die with them; the sailors who do not hear them go on rowing). The myth illustrates the modern science of biological signals, the contradictory or alternate messages of which determine cell behavior.

With apoptosis as the key concept to the understanding of immunity as interference with cell suicide, we have to pay attention to the merging of two functions that are historically claimed by immunologists: infection control and cancer surveillance. The molecular description of a cycle of gene repressors leading to cellular death enables reconsideration of Burnet's past effort to associate them. The new orientation in anti-infectious strategy is no longer the mere destruction, either chemical or cellular, of the pathogen, but the exploitation of programmed suicide, by sending the cells a signal that is ordinarily repressed. The link between potent life and death metaphors, and the schemes of thought favored by scientists will remain a matter of debate for those who wish to elucidate the mechanisms of discovery and serendipity in research.

THE MOLECULARIZATION OF VACCINOLOGY

If new immunology is still uncertain about its theoretical foundations (is the self more than philosophical platitudes?), can it at least rely on its medical practical successes in the molecular era?

'The 1990s will be remembered as the decade of vaccines', a researcher from Connaught laboratories exclaimed in 1995, in Canada, during a congress on vaccines (Klein 1996, p. 295). And he went on to explain how research would update the classic vaccines and deliver new ones. The vaccine model had unified and stimulated the field of immunity studies and powerfully motivated scientists and governments. But the old models of war against germs appeared inappropriate in a sophisticated era where cognitive modes of thought tended to replace bellicose metaphors (Fox-Keller 1995).

Although the notion of species fixity has always been controversial (Amsterdamska 1987), vaccines were first conceived on the basis of a supposedly stable bacterial order. This order has been shattered. The constant mutations of flu viruses oblige us to invent new vaccines each winter. Bacteria or viruses, we have learnt, contain revertant individuals displaying the virulence of wild strains, or a new virulence, after mutations induced by the environment or through hybridization with other strains in a propitious environment. Reversion to virulence and polio cases that happen after oral immunization are probably the result of recombinations in the gut of the three vaccinal strains, or possibly between vaccinal viruses and other enteroviruses. A genetic drift makes strains of pertussis, the agent of whooping cough, diverge from the vaccinal prototypes, increasing the burden of the vaccinal enterprise.

The whole historical enterprise of immunization, notwithstanding its numerous 'hazards', was rather successful in the long run. Yet, molecularization was expected to fare better still and provide safer vaccines in diseases that were already controlled. Overall, it was advertised as coping with diseases refractory to immunization, such as leprosy or dengue fever, or new plagues such as AIDS.

Molecular vaccinology stands in sharp contrast to the former empirical methods of pathogen attenuation and is celebrated as the achievement of Landsteiner's ideal, with the replacement of crude preparations by molecules of exquisite specificity. Technical advances in gene splitting, gene sequencing, and protein engineering would allow the identification and optimization of new protective antigens against bacterial, viral, and parasitic diseases, on the basis of the most recent knowledge on the immune response pathways.

As vaccines played an important role in the popularity of immunology, although the development of immunology followed rather than caused the advent of early vaccines, molecularization – the shift from mere empiricism to rational design – was considered as the historical opportunity for immunology to produce at last ideal vaccines.

Several pathways offered for molecularization deserve comment:

- The first is the cloning of genes coding for virulence factors, islets grouping all sites involved in cellular invasion, toxin production, for the rational development of knock-out bacterial strains, or their introduction in vectors (Kourilsky 1987). Although BCG, administered soon after birth, avoids meningitis and disseminated infections in infants, it protects imperfectly against pulmonary tuberculosis in adult life. The new BCG projects plan to replace one of the most controversial vaccines by a modern one (Palfy et al. 1999).

- The second pathway is the recombinant subunit vaccines, the prototype for which is the hepatitis B vaccine.
- Genetic immunization is presented as an elegant way of making muscular tissue produce a vaccine.
- Finally, synthetic vaccines would mark the peak of innovation. The computerized invention of vaccinal structures, e.g. polypeptidic antigens, flatters the esthetic taste and comforts the quest for vaccines tailored to each individual's genetic make-up and lifestyle.

Adenoviruses were the first vectors in favor. They had been used as oral vaccines for respiratory infections since 1969. Then came the poxviruses (Panicali and Paoletti 1982). Cowpox, in use for two centuries, had allowed smallpox eradication. The first recombinant successfully produced as a vaccine was the canarypox rabies vaccine for dogs.

One of the great successes of molecular immunology was the production of recombinant vaccine against hepatitis B (Blumberg 1975). The research was fueled by anxiety linked to the use of hepatitis B carrier plasmas and the threat of transmission of an unknown virus undetected by the tests and undestroyed by inactivation techniques (Muraskin 1995). The recombinant vaccine obtained in vitro by expression of hepatitis B antigen in yeasts was licensed in 1986 (McAleer et al. 1984). Polysaccharidic vaccines protecting against capsular bacteria such as *Neisseria meningitidis* or *Haemophilus infuenzae* were also produced.

The programs have led more to a gathering of an unprecedented amount of information on immunity than to solving the practical issues that they had in mind. In spite of the adoption of current methods of molecular biology, reviews of the processes employed concluded that the choice of various preparations was still empirical. More clinical trials, especially in infants, were necessary to help understand 'conjugate immunology' (Moreau 1996, p. 148).

Expression of the foreign antigen by the carrier is not sufficient to elicit an immune response. The presentation of the antigen to the immune system depends on its physical location on the bacterial surface, and its accessibility is crucial for the magnitude of the immune response. Rather than choosing attenuated pathogens, it has been suggested that commensal microorganisms should be used to deliver vaccine antigens, but they then have to compete with the local flora. Molecular biology forces us to enter a realm always further away, toward an artificially produced environment. This strategy requires surveillance of its short- and long-term consequences, in terms of infection, morbidity, and mortality rates. Are we prepared to sustain this challenge, especially in countries where health services are inadequate or disorganized through internal or external conflicts?

In spite of its proponents' enthusiasm, it appears that the revolution has not yet borne all the expected fruit. Parasitic diseases do not give way, even the leishmaniases that had fostered well-founded hopes, since the early attempts at empirical immunization went back to the eighteenth century in the Middle East. The WHO has recently encouraged clinical trials for a modernized version of this legacy of the past (Mudabber 1989).

Genetic vaccines, although made attractive by their simple, cheap, and easy manufacture, seem to be inefficient and raise numerous queries about the advent of genes into the microenvironment of the body. The old adjuvant, alum, which is still in use, was recently charged as provoking untoward effects. There is an agreement about its replacement by synthetic molecules: this means that research starts again from zero, with clinical trials required for assessing the new adjuvants.

The rational approach paradoxically does not guarantee that the deleted bacterium will produce the desired immunity. Although usually passage of strains through animals leads to attenuation, biological engineering modifies pathogenicity without offering parallel constant immunogenicity. In any case, the new vaccine must be tested in phase I studies, without the benefit of more than one century of experimentation and results in the field of immunity. Molecularization leads to purity that is not synonymous with antigenicity, an event that could be expected, after revisiting early studies on haptens by Karl Landsteiner at the turn of the twentieth century. Landsteiner expressed the necessity of coupling small well-known chemicals, which he labeled as 'haptens', with large molecules playing an elusive role (carriers) in the triggering of the immune response.

The cytoxic lymphocyte (CTL) epitopes, supposed to provide clues for the treatment of cancer and of chronic infectious diseases, are not necessarily potent antigens, and subunit and peptide vaccines often behave as poor antigens.

The unification of vaccines under the banner of molecular immunology has not been completed to date, never mind the economic problems linked to the cost of new technologies and the difficulty of replacing old vaccines by new ones, bearing in mind modern regulations about innovation and their approval.

If molecularization has not resulted in a general program for safe and effective vaccines, is this for structural or historical reasons? The optimists argue that we just have to wait for appropriate tools and molecules, exquisite specificity retaining its long-term promises. The pessimists argue that immunization has reached its historical limits and will fail when confronted with pathogens that have evolved, or rather coevolved, with potent mechanisms for using the organism's cells and the immune system itself to survive and direct the components of the organisms to their profit: incorporation in the cell genome, fixation on receptors, use of chemokines as growth factors or decoys. Failures would occur

inexorably and the number of invading viruses (the 'emergence' phenomenon) would rise, to the point where it may be discussed whether we have reached a limit along this pathway in our capacity to deal with infections (Moulin 1996a). Have we not dealt in the first place with the easiest-going pathogens, those secreting a toxin (diphtheria, tetanus)? Does it remain possible to reach those that are more or less integrated into the nuclei of our cells? Killing infected cells may go too far and trigger an array of inflammatory phenomena.

This could change the very meaning of immunization and point to relative rather than absolute prevention, as is actually the case in AIDS trials where vaccine may be administered in the course of infection, to help the organism to cure the disease or reduce its severity. But this change in the biological meaning of vaccines would entail a dramatic revision in both popular and medical perceptions of immunization as a tool of public health, and would probably undermine its current applications.

THE IMMUNE SYSTEM AS A SUBSYSTEM OR A PART OF THE WHOLE

Jerne and others had already described formal analogies between the nervous and the immune systems, and suggested mathematical modeling for the sake of comparison (Lefkovits 1980). Molecularization of immunology, with the emergence of multiple families, has led to the relativization of the frontiers between organs and awareness of the narrow relationships among organs, cell lines, and systems. Compared with the nervous system, its paragon and model, the immune system, is first characterized by the mobility of its elements. Fridman (1992) called it the mobile brain. Cells of the immune system move continuously and this movement is essential for immunosurveillance and clonal selection, 'in the sea of microbes, toxins, parasites and mutagens we call Earth' (Anderson 1990, p. 14).

The immune system shares more than cursory similarities with other systems such as the endocrine or nervous systems. Bidirectional communication between them seems to occur as a result of common hormones and receptors. Revisited in the era of molecular biology, the list is impressive and ever increasing. Not only do neuroendocrine and immune tissues produce, communicate, and regulate a battery of informational molecules, but also there is growing evidence that these systems may use similar, if not identical, molecules to achieve their ends. Receptors for neuroendocrine molecules on immune cells and for lymphokines on neuroendocrine cells provide ample means for the two systems to interact. Cytokines are secreted by immunocompetent and glial cells. Neuroendocrine factors such as corticotropin-releasing hormone or growth hormone could have been qualified as cytokines if they had initially been described by immunologists, and molecules that were seemingly typically immune could have been qualified as neuropeptides if there had been timely identification by neurobiologists.

Receptors for cytokines present in the brain emit information that modulates the reaction to infection by pathogens. There are ligands for norepinephrine (noradrenaline) and other neuropeptides on the surface of macrophages, lymphocytes, and other immunocompetent cells. Immunoblotting has allowed the identification of receptors on immune and neural cells, ascertaining their molecular identity. β-Endorphin, which participates in analgesia during stress, can link with opioid receptors on lymphocytes (Dantzer et al. 1999). The humoral immune response is accompanied by an activation of the hypothalamic–hypophyseal–cortical–adrenocorticotropic axis and the rise of cortiscosterone in blood. A lesion of the hypothalamic–hypophyseal axis by radiofrequency suppresses the cytotoxic activity of natural killer (NK) cells in mice (Blalock 1997). Immune cells behave like a sensorial organ that is able to convey information to the brain.

These data suggest the importance of taking seriously not only the unity of the organism, but also the difficulty of interfering with its inner organization.

IMMUNOLOGY OF INFECTION: A POST-MODERN PERSPECTIVE

The immune system is a biomedical construct, the elaboration of which has proceeded over several periods, during which the understanding of its functions and its composition have been radically modified: after defense against germs, these functions were the self/nonself discrimination, tumor surveillance, participation in homeostasis, etc.

During the second half of the twentieth century, the microbial element lost its importance as the most immediate correlate of immune function, and the immune system appeared more and more able to respond to various stimulations and to interact with other systems that share the bodily space.

As we began to consider the complexity of microorganisms, and their considerable flexibility, resistance, and capacity to escape, disenchantment has set in to match the ingenious nature of parasites and viruses, strategies have become more sophisticated, clever, and costly. This observation opens on human history and evolution of the living world that coexist and collide under our eyes.

How will the new immunology meet the challenge of the dark infectious age agents? Not only had the microbial world accrued diversity, but also the pathways of pathogens into the organism were known to be multiple: how does the immune system deal with pathogens ranging from telluric bacteria, such as the tetanus bacillus secreting a toxin that can be absorbed *per os* without causing the least trouble, to viruses able to

invade the genome of the immune system and remain there silent for long periods of time before bursting out?

The return of infectious diseases has prompted the need for fresh knowledge and the urge to deepen both immunological and genetic components of the immune response. Not only did it revive the idea that heredity and immunity, or vertical and horizontal transmission, are two faces of the same coin, it also led to the idea that immunity is strongly integrated into many physiological and pathological responses.

With the new challenges posed by the return of infectious diseases, now that we are aware of the two-edged nature of most of our therapeutic tools and the ambivalence of most drugs, we can start to appreciate how the scientific revolution that is ritually celebrated has so far been incomplete, and to measure the extent of the work that lies ahead of us. There is a huge need for specific studies, but integrated approaches are also badly needed. It is a concern for the author of this chapter that the historical and philosophical approach attempted allows us to cast a critical glance over our accumulated knowledge and the seemingly impressive breakthroughs that deepen our knowledge, but also to move the future targets forward.

There is no such thing in history as a return to a former perspective. Even if the rallying cry of the fight against infectious diseases has sounded over these last few years for immunologists, it is by no means a return to the past. Contemporary immunology, with an emphasis on infectious diseases, can indeed be redefined as an immunity of infection rather than immunology of infections. Although infectious diseases are many, this chapter on the recent past of immunology spells 'infection' in the singular. Infection does not point to a separate chapter on pathology, but is a central episode corresponding not only to traditional infectious diseases but to many other disorders, from poorly understood autoimmune syndromes to diseases once labeled neurological, endocrine, or otherwise, and cancers. The advances made in the understanding of the immune system illuminate some crucial events in the genesis of disease and the fabric of normal life through all kinds of encounters with pathogens both internal and external. The immune system can be assimilated, in a sixth sense, for sensing pathogens, the key organ of interaction between the organism and its environment. The central position of immunology today in medicine echoes the centrality of infection as a crossroads in the economy of the organism.

Phagocytes part 1: Macrophages

GORDON D. BROWN AND SIAMON GORDON

Origins of macrophages	1	Subversion of macrophage function by pathogens	10
Recognition of pathogens	2	Role of macrophages in homeostasis	10
Ingestion of microbes	4	Macrophage-induced pathology	11
Antimicrobial mechanisms	5	Conclusion	11
Macrophage activation	7	Acknowledgments	12
Secretion of soluble mediators and other factors	7	References	12
Antigen presentation	9		

Macrophages (Mϕ) play an essential role in anti-infectious immunity. They are key players in the innate immune system, detecting and responding to microbial invasion, restricting the spread of microbes, and recruiting other immune cells to the site of infection. Mϕs can act as accessory cells in secondary lymphocyte activation and as effector cells in cell-mediated immunity, and participate in humoral immunity by eliminating foreign antigens. The functions of Mϕs are enhanced when these cells are activated; thus activation represents a crucial step in anti-infective immunity and defects in this process result in an increased susceptibility to pathogens. Mϕs produce a number of anti-inflammatory molecules, which contribute to the resolution of inflammatory responses, and are also involved in many essential homeostatic functions, such as the clearance of apoptotic cells.

In this chapter we present an overview of Mϕ functions, as they relate to anti-infectious immunity. We describe the origins and types of Mϕs, the mechanisms they use for microbial recognition, uptake, and killing, as well as describing their interactions with the adaptive immune system through the release of cytokines and other soluble factors, and through the presentation of antigens. We explore Mϕ activation, their role in homeostatic processes, as it relates to infection, and briefly discuss Mϕ-induced pathology. With such an important role in anti-infective immunity, the Mϕ also provides an ideal niche for pathogens able to modify Mϕ functions, and we demonstrate some of the mechanisms that pathogens use to achieve these goals.

ORIGINS OF MACROPHAGES

Macrophages originate from blood monocytes which are generated in the bone marrow from monoblasts and promonocytes. Monocytes enter the bloodstream constitutively throughout life, accounting for 1–6 percent of the total normal adult white blood cell count (Ross and Auger 2002). These cells leave the bloodstream by adhering to endothelial cells through interactions of a variety of surface receptors, including β_1- and β_2-integrins, such as VLA-4 and LFA-1, which interact with immunoglobulin-domain-containing endothelial receptors, such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) (Springer 1994; Yusuf-Makagiansar et al. 2002). Pathogen-derived molecules, such as lipopolysaccharide (LPS), and a number of inflammatory cytokines cause upregulation of these receptors, resulting in increased leukocyte delivery to sites of infection and inflammation (Roebuck and Finnegan 1999). After adherence, monocytes pass between the endothelial cells by diapedesis, involving interactions with other molecules such as CD31 (platelet endothelial cell adhesion molecule-1 (PECAM-1)), and subsequently migrate into tissues where they differentiate into mature macrophages (Muller and Randolph 1999). A diagrammatic repre-

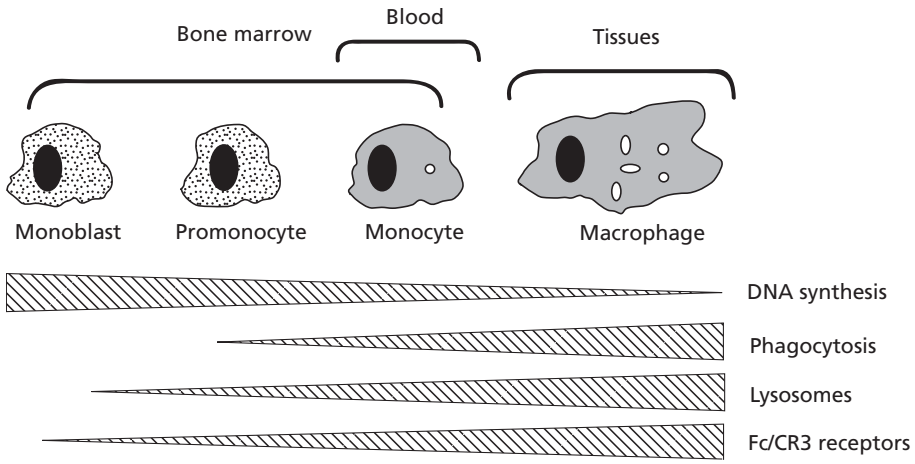

Figure 1 *The origins and characteristics of cells giving rise to tissue macrophages. (Adapted with permission from Auger and Ross 1992.)*

sentation of the development of tissue macrophages and some of their characteristics is shown in Figure 1.

Tissue macrophages display great functional and morphological heterogeneity, depending on their functional state as well as their interactions with other cells and molecules in the local microenvironment (Gordon 1999, 2001, 2003b). The characterization of these cells has been made possible by the development of tools such as monoclonal antibodies that recognize distinct macrophage proteins (Gordon et al. 1992; Gordon 1999). Resident populations of Mϕs are found at or close to portals of entry (e.g. lung, gut, skin), as sinusoidal cells in liver (Kupffer cells), as stromal cells in bone marrow, and spleen and lymph nodes, and as part of the neural parenchyma (microglia) (Crocker et al. 1991; Perry et al. 1993). They display considerable phenotypic microheterogeneity, e.g. in splenic red pulp, white pulp, and marginal zone, where blood-borne pathogens interact with specialized Mϕ subpopulations and other immune cells (Kraal 1992; Martinez-Pomares and Gordon 1999). An analogous subpopulation of Mϕs is present in the subcapsular region of lymph nodes, encountering potential antigens and dendritic cells in afferent lymph. An example of macrophage heterogeneity in the spleen is shown in Figure 2.

Monocytes can also differentiate into dendritic cells (DCs), specialized cells that have the unique ability to migrate out of tissues to secondary lymphoid organs and prime naïve T cells (Mellman and Steinman 2001). These cells are found in most tissues, such as the Langerhans' cells of the skin, and display functional and morphological heterogeneity. They have two distinct functional stages, based on their ability to take up and process antigens (the immature stage) and their ability to migrate to the lymphoid organs and activate antigen-specific T and B cells, directing the generation of the adaptive immune response (the mature stage). Although possessing unique abilities, many of the functions of DCs are similar to those found in macrophages, including their ability to recognize and internalize pathogens and their ability to recruit other immune cells, such as macrophages, neutrophils, natural killer (NK) cells and immature DCs, to the sites of infection. Aspects of this are covered below and in other chapters.

RECOGNITION OF PATHOGENS

During initial infection, the recognition of pathogens by macrophages and other phagocytes is reliant on germline-encoded molecules, termed pattern recognition receptors (PRR) (Janeway 1992). These molecules do not undergo the somatic mutation characteristically required by the adaptive immune response. As the name implies, these receptors recognize conserved microbial structures (the pathogen-associated microbial patterns (PAMP)), such as lipoteichoic acid (LTA) of gram-positive bacteria, LPS of gram-negative bacteria, and β-glucan of fungi. By recognizing these conserved structures, the host can recognize a variety of microbes with a limited set of receptors. Expression of these receptors is varied in different macrophage populations and can also be regulated by cytokines and other immune-modulating agents, including microbial components such as LPS (McKnight and Gordon 1998). In addition to pathogen recognition, the PRRs also determine the mechanism and route of cellular uptake, the response mediated by the Mϕ, and ultimately the immune response generated toward the pathogen.

The PRRs are either found free in the serum, as membrane receptors, or located intracellularly. A list of selected molecules in each of these classes, as well as their microbial ligands, is shown in Table 1. The serum-derived PRRs include the collectins, pentraxins, and complement, which coat the microbe (opsonization), allowing recognition and binding by opsonic receptors on host phagocytes. Specific antimicrobial antibodies,

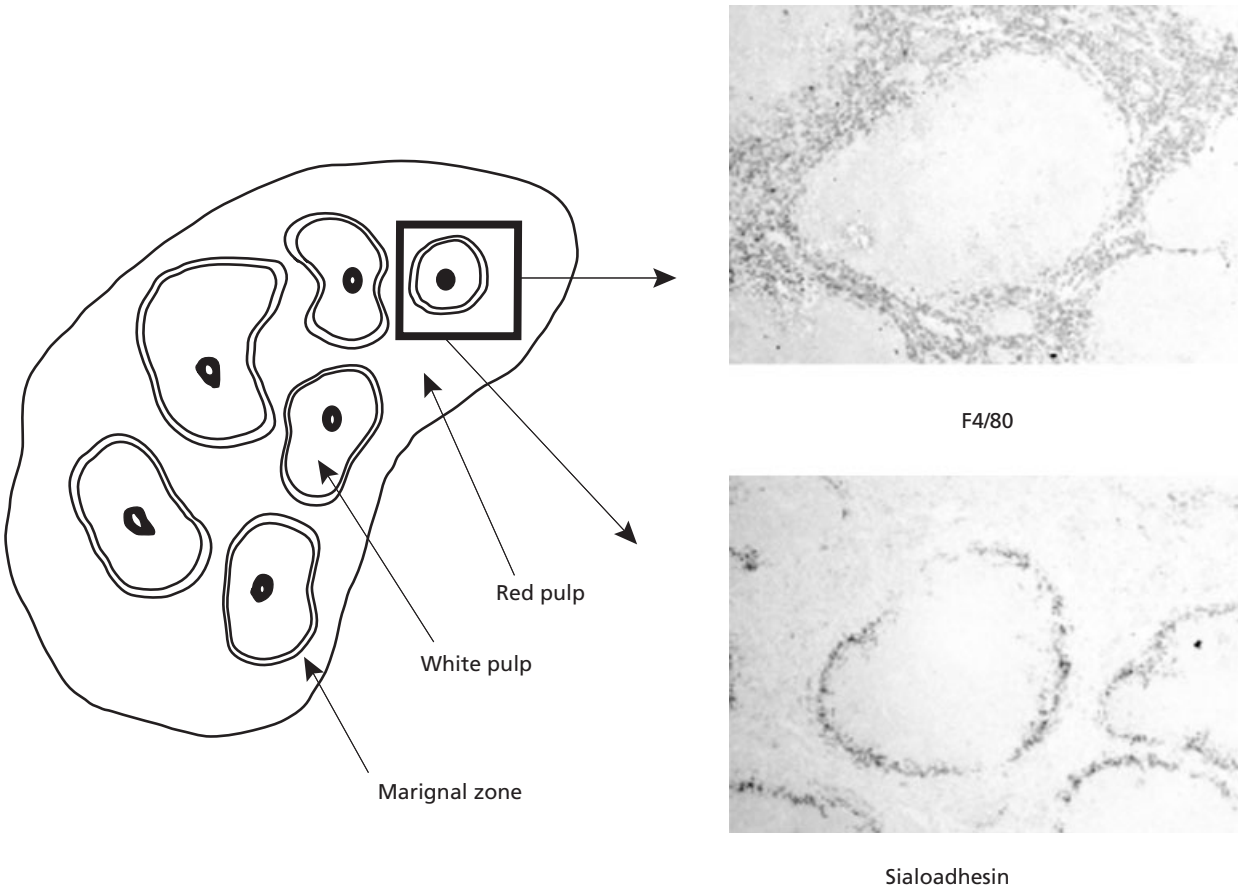

Figure 2 *Mouse spleen showing macrophage heterogeneity. Red pulp macrophage (Mϕ) can be detected with F4/80, whereas metallophilic Mϕs (in the marginal zone) can be detected with the anti-sialoadhesin antibody (3D6). (Images courtesy of Dr Luisa Martinez-Pomares, University of Oxford.)*

produced after the induction of acquired immunity, enhance the opsonic recognition of microbes. Although some of the opsonic receptors on host cells have been described, including the complement receptors and those that recognize the Fc portion of antibodies (the so-called Fc receptors) (Ravetch and Clynes 1998), many are still unknown. The nonopsonic or direct recognition and binding of microbes is mediated by a variety of membrane-bound PRRs on phagocytes, including classic and nonclassic C-type lectins, leucine-rich proteins, scavenger receptors, and integrins. Intracellular PRRs include the recently described 'nucleotide-binding oligomerization domain (NOD)' proteins as well as a variety of proteins involved in the recognition of viruses. It should be remembered that the in vivo recognition of microbes probably involves coordinated recognition by many of these receptors, e.g. binding of *Mycobacterium tuberculosis* to macrophages has been shown to involve the complement and mannose receptors, as well as CD14 and the surfactant protein A (collectin) receptor (Ernst 1998).

Although less well characterized, molecules other than the PRRs can also be used by pathogens to bind to and/or enter Mϕs. This is especially true for viruses that make use of cellular molecules, such as the proteoglycans, or other receptors, such as the chemokine receptor CCR5 used by HIV (Miller and Gordon in press). The use of these 'nonimmune' molecules to gain entry into cells enables pathogens to bypass the antimicrobial effects normally generated by the PRRs.

While the binding and internalization of microbes is mediated by various PRRs, generation of the appropriate responses has been ascribed to a recently identified family of receptors, the Toll-like receptors (TLRs). These receptors were originally identified by homology to a receptor in *Drosophila*, and are a family of receptors with homology to the interleukin (IL) 1 (IL-1) receptor (Hoffmann and Reichhart 2002). The various TLR family members can distinguish between various pathogens, often by acting in combinations, and initiate signaling cascades similar to those induced by the IL-1 receptor, via MyD88 and IRAK to activate the factor NFκB, resulting in the production and/or release of proinflammatory mediators and cytokines (Medzhitov 2001; Underhill et al. 1999; Ozinsky et al. 2000). Although a number of TLRs and their ligands have been identified, they all appear to

signal via the same pathway and it is therefore not yet understood how specific responses to each pathogen are initiated. There is some evidence that response specificity is mediated by specific intracellular adaptors, such as TIRAP, and also by the PRRs involved in recognition and binding (Engering et al. 2002; Horng et al. 2002).

It should be remembered that Mϕs also possess many other surface receptors that play a role in the response to infection, but are not involved in microbial recognition. These receptors include the cytokine and chemokine receptors, as well as receptors involved in migration, adhesion, and antigen presentation. Some of these aspects are covered in more detail below and in later chapters.

INGESTION OF MICROBES

Macrophages have a prodigious capacity to ingest microbes and are capable of engulfing very large particles. This ability may be the result of their, apparently unique, ability to utilize membrane from the endoplasmic reticulum (ER) for this uptake (Gagnon et al. 2002). Ingestion is initiated by binding of microbes to the Mϕ surface receptors, which triggers the transmembrane activation signals leading to their internalization. For microbes larger than 0.5 μm, internalization occurs through a heterogeneous actin-dependent process called phagocytosis (Aderem and Underhill 1999). Many of the details of these processes are incompletely understood and made more

complex by the fact that microbes are recognized by more than one receptor, each of which may be dictating a different mechanism of uptake. The receptors themselves may also interact with other surface receptors, such as CD172a (signal regulatory protein alpha (SIRPα)) (Oldenborg et al. 2001), either stimulating or inhibiting uptake.

The understanding of phagocytosis, first observed by Elie Metchnikoff in the 1890s, is currently based on the study of two receptors, the Fcγ and complement receptors. The Fcγ receptor (FcγR) mediates what is known as the zipper model of phagocytosis, whereby actin-rich pseudopods extend over the particle surface through the sequential binding of cell surface receptors to the microbe, ultimately engulfing the entire particle (Griffin et al. 1975, 1976). This process is initiated by receptor clustering, occurring from interactions with the microbe, and leads to the phosphorylation of tyrosine residues in specific motifs (the immunoglobulin gene family tyrosine activation motifs) of the cytoplasmic tail of the receptor (Daeron 1997). These phosphorylation events are dependent on cytoplasmic enzymes, the src kinases, and result in the sequential recruitment and signaling via a variety of other molecules, including Syk, Cdc42, and Rac, which results in actin assembly, membrane protrusion, pseudopod extension, and finally closure of the phagocytic cup (Caron and Hall 1998; Aderem and Underhill 1999).

Complement receptor (CR)-mediated phagocytosis is less well understood but is known to require an additional stimulus to occur, such as tumor necrosis factor α (TNF-α) or attachment to extracellular matrix proteins. In contrast to the FcγR, the particle is not engulfed by pseudopods but rather appears to sink into the cell, forming a phagosome where the membrane is less adherent, held by point-like contacts to the microbe (Kaplan 1977; Aderem and Underhill 1999). CR-mediated phagocytosis also requires intact microtubules, uses different signaling molecules, such as Rho, and is not blocked by inhibitors of tyrosine kinases (Allen and Aderem 1996; Caron and Hall 1998).

Microbes can be ingested through a variety of other mechanisms, including macropinocytosis, coiling phagocytosis, and endocytosis. Macropinocytosis describes a process whereby membrane ruffles form a large spacious vacuole around the adjacent microbe, leading to subsequent ingestion (Rittig et al. 1999). In coiling phagocytosis, there is an initial extension of a single pseudopod, which wraps around the microbe. Subsequent pseudopods form, giving the characteristic whorl-like appearance, which ultimately fuse to form the phagosome (Rittig et al. 1999). Endocytosis is a heterogeneous group of cellular processes used for the internalization of particles smaller than 0.5 μm, such as viruses, and includes caveolae- and clathrin-mediated endocytosis (Gruenberg 2001; Shin and Abraham 2001; Sieczkarski and Whittaker 2002).

Receptor-mediated endocytosis and phagocytosis are used for homeostatic functions by Mϕ and to clear up the debris released by infection, including necrotic and apoptotic cells. In addition, these mechanisms are used or subverted by a variety of pathogens, the study of which has given many insights into the molecular mechanism underlying these processes.

After internalization, the phagosome matures through a number of sequential steps involving interactions with the endocytic pathway (Desjardins et al. 1994). This consists of extensive vesicle budding and fusion, controlled by a variety of cytoplasmic proteins including the rab guanosine triphosphatases (GTPases) (Aderem and Underhill 1999). During maturation the phagosome moves along the microtubule network from the periphery to a perinuclear location. As it matures, the phagosome acquires hydrolytic enzymes, such as cathepsin-D, and the proton pump adenosine triphosphatase (ATPase), which contributes to a lowering of the phagosomal pH. The late stages of maturation involve fusion with lysosomes generating a low pH phagolysosomal compartment containing a variety of degradative lysosomal hydrolases (Alvarez-Dominguez et al. 1999). The process of maturation therefore generates an increasingly antimicrobial environment in which the ingested microbe is ultimately killed and digested. A simplified schematic diagram of these processes is shown in Figure 3.

ANTIMICROBIAL MECHANISMS

Macrophages possess a variety of antimicrobial mechanisms including the use of toxic metabolites, enzymes, and peptides, as well as through physical restraint of the pathogens, by ingestion into phagosomes, or through the formation of a granuloma. Most organisms are killed within the phagosome after phagocytosis, through a number of mechanisms that can work synergistically. The maturing phagosome generates an increasingly antimicrobial environment, achieved through lowering of the phagosomal pH, limitation of nutrients required for microbial growth, and generation of reactive metabolites. After fusion of the phagosome with lysosomes, there is also the acquisition of hydrolytic enzymes, antimicrobial proteins, and peptides, such as the membrane-permeabilizing peptide defensins, which have a broad spectrum of microbial targets, and lysozyme, which attacks the peptidoglycan layer of bacterial cell walls.

The confinement of microbes within the phagosome acts as a physical barrier to the microbe, limiting the availability of essential nutrients required for microbial growth, such as iron. The supply of nutrients to the phagosome is further restricted by active mechanisms within the cells. The transferrin receptor, for example, which transports iron via the endosomal pathway, is downregulated upon infection whereas another molecule, natural resistance-associated macrophage protein-1

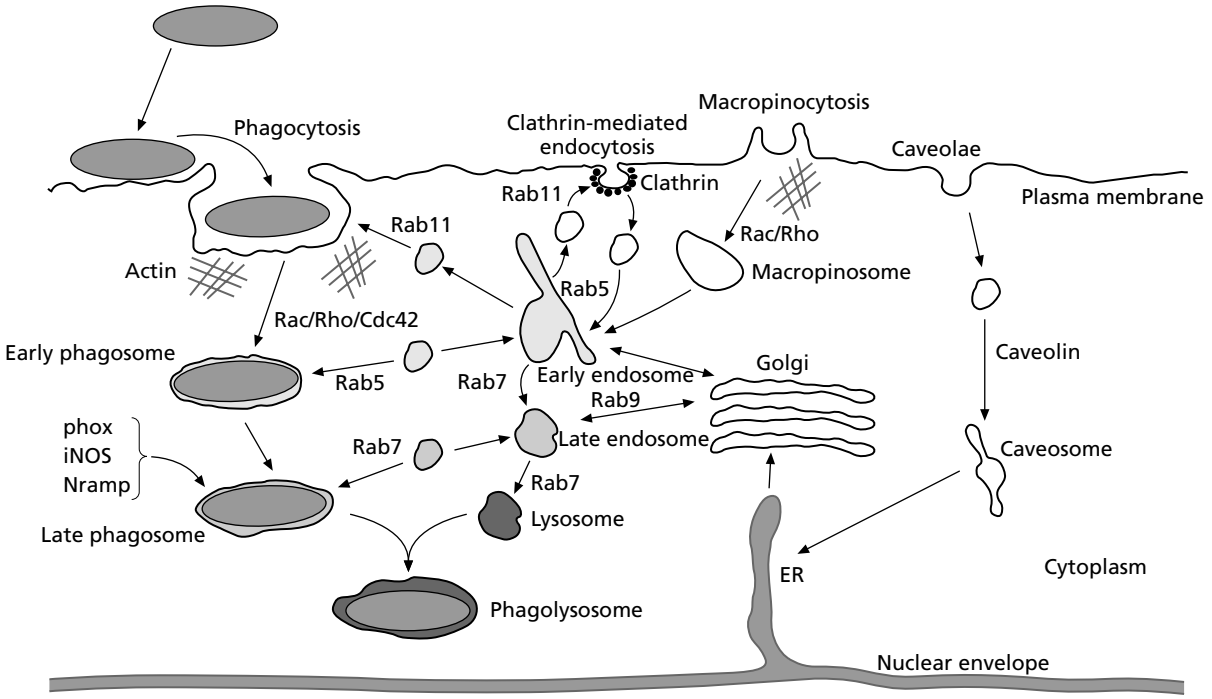

Figure 3 *A schematic representation depicting the various routes used by macrophage (Mϕ) to internalize microbes. Some of the molecules associated with this process are also indicated. (Adapted in part from Sieczkarski and Whittaker 2002.)*

(Nramp-1), is recruited to the phagosome, ensuring removal of iron and other essential divalent cations (Gruenheid et al. 1997; Sunder-Plassmann et al. 1999; Forbes and Gros 2001).

The production of reactive oxygen intermediates (ROIs), described as the respiratory burst of Mϕs, is a very efficient antimicrobial defense. Superoxide ion ($O_2^{-\bullet}$) is generated by the activated, membrane-associated, protein complex, the phagocyte reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (phox), which transfers electrons from NADPH to O_2. Toxic oxidants, including hydroxyl radicals and hydrogen peroxide, are then generated in the phagosomal lumen, and kill the internalized organism (Hampton et al. 1998). The phox proteins may also assemble in the plasma membrane, resulting in the generation of extracellular toxic oxidants, which may also contribute to pathology. Superoxide ions can also act as a signal for the activation of granule proteases in neutrophils (Reeves et al. 2002). Activation and localization of the oxidase complex are determined by the cellular receptors involved in recognition of the pathogen, and involve numerous signal transduction cascades that result in phosphorylation of one of the cytosolic phox proteins ($p47^{phox}$) (Karlsson and Dahlgren 2002). Chronic granulomatous disease (CGD) is a disease characterized by recurrent infections with a number of pathogens, and results from mutations in the phox proteins, highlighting the importance of this antimicrobial mechanism for the host (Goldblatt and Thrasher 2000).

Myeloperoxidase (MPO) is a major neutrophil granule protein that is also found in monocytes. MPO generates hypochlorous acid from hydrogen peroxide, one of the most potent antimicrobial agents produced (Winterbourn et al. 2000). Although MPO is not produced in Mϕs, it can be taken up via the macrophage mannose receptor and is known to augment macrophage antimicrobial activity (Shepherd and Hoidal 1990; Marodi et al. 1998).

The inducible nitric oxide synthase (iNOS) of phagocytes is another important enzyme contributing to the antimicrobial actions of Mϕs. Induction of iNOS leads to the production of nitric oxide (NO), through the oxidative deamination of l-arginine, which subsequently reacts with superoxide or thiol groups to produce antimicrobial compounds, such as peroxynitrite and nitrosothiols (Burgner et al. 1999). The production of NO by iNOS requires homodimerization and interaction with many other molecules, including calmodulin, and NADPH. Microbial products, such as LPS, and cytokines, such as TNF-α or interferon γ (IFN-γ), can act either individually or synergistically to induce the production of iNOS (MacMicking et al. 1997). The use of iNOS inhibitors and knockout mice has clearly demonstrated the importance of this antimicrobial mechanism in the control of many infections (Wei et al. 1995).

Macrophages possess two other notable features that play a role in antimicrobial activities, that of cellular activation and apoptosis. Apoptosis, or programmed cell death, is an important defense mechanism limiting the spread and growth of intracellular organisms. Mϕs, which themselves undergo apoptosis during certain infections, are key players in the clearance of apoptotic bodies and are able to induce this process in other cells (Geske et al. 2002). The role of apoptosis in infection is not always so clear, however, because in some cases apoptosis appears to favor the pathogen (Weinrauch and Zychlinsky 1999; Navarre and Zychlinsky 2000). Finally, macrophage activation is extremely important for the control of infection, because activation, via cytokines or microbial products, enhances the antimicrobial activities of these cells.

MACROPHAGE ACTIVATION

The ability of macrophages to become activated is critical for the resolution of infection. This term has been loosely applied to describe the selective, stereotypical responses of Mϕs to different stimuli, mainly of a microbial or immunological nature. Recent gene array studies have started to illustrate the diversity of genes expressed in various infectious and other experimental models. Earlier phenotypic characterization made it possible to discern the following types of cell activation: innate activation, classic immune activation, and alternate activation. Finally, the control of this process, through the deactivation of Mϕs, is critically important to reduce pathology.

Innate activation, induced by microbial products and intact microorganisms, is mediated by specific receptors and signaling pathways described already, and results in altered pro- and anti-inflammatory metabolite secretion, enhanced expression of co-stimulatory molecules, and induction of plasma membrane receptors such as MARCO, a type A scavenger receptor (Gordon 2001). Thus, antimicrobial and immune functions are induced, as well as cell migration and dendritic cell maturation.

Classic immune activation was originally described by Mackaness as enhanced, antigen non-specific, antimicrobial activation of Mϕs during *Listeria monocytogenes* and BCG (mycobacterial) infection (Gordon 1999, 2003b). This can now be ascribed to IFN-γ, acting on specific Mϕ receptors and their signaling pathway (Gordon 1999, 2003b). IFN-γ is produced by natural killer (NK) cells and activated T lymphocytes in response to cytokines produced by antigen-presenting cells (APCs), IL-12, IL-18, and IL-15. Genetic studies in mouse and humans have confirmed the importance of this pathway in cellular immunity to infection by mycobacteria and other selected pathogens. Secondary deficiency contributes to opportunistic infections in AIDS. In addition, IFN-γ induces major histocompatibility complex class II (MHCII) and iNOS expression and primes Mϕs to secrete high levels of mediators in response to microbial stimuli.

Alternate immune activation can be induced by the cytokines IL-4 and IL-13, acting on a common receptor subunit and resulting in a distinct program of gene expression in Mϕs to promote humoral immunity, especially against extracellular parasites (Gordon 2003a). Phenotypic markers include elevated MHCII, enhanced mannose receptor, and, in some situations, giant cell formation. Certain chemokines (MDC and TARC) and a range of other markers are also selectively upregulated. Inducible NOS is downregulated, whereas l-arginine metabolism is switched to favor collagen production by fibroblasts, and repair.

Deactivation is mediated by cytokines such as IL-10 and transforming growth factor β (TGF-β) which profoundly downregulate Mϕ proinflammatory, immunological, and cytotoxic activities (Gordon 2003a). The balance between activation and deactivation is critical in preventing host injury, as illustrated in inflammatory bowel disease and genetic deficiency of the above cytokines. New findings have highlighted the importance of inhibitory receptors on the Mϕ surface, such as SIRPα, which limit activation of Mϕ. Distinct receptor pairs that regulate Mϕ activation include CD200/CD200R – microglia become spontaneously activated in CD200-deficient mice; experimental autoimmune disease is regulated, in part, by this pathway. Important intracellular regulatory systems include the suppressors of cytokine synthesis (SOCS) family and type I interferons. The uptake of apoptotic cells downregulates inflammatory responses of Mϕs.

SECRETION OF SOLUBLE MEDIATORS AND OTHER FACTORS

In addition to the secretion of ROIs, described above, Mϕs produce and secrete a variety of other products either constitutively or after stimulation. These include factors that are involved in homeostasis, such as pro- and antiangiogenic factors controlling vascular supply, or those, such as lysozyme, that are involved in combating infection. Other secretion products include enzymes, such as lysosomal hydrolases, proteases, and lipases, some of which help to maintain extracellular matrix balance, and promote and interact with plasma protein cascades (coagulation, fibrinolysis, complement, kinin generation) in response to injury (Gordon 2003b). Mϕs produce complement components, which opsonize microbes and are major producers of arachidonic acid intermediates (Ross and Auger 2002).

Macropages produce cytokines and chemokines, which recruit other immune cells to the site of infection and which, along with antigen presentation to lymphocytes, help direct the generation and type of the adaptive immune response. Cytokines are central molecules of the immune response, forming a complex network that

Table 2 *Selected cytokines produced by or having an effect on macrophages (Mϕs)*

Cytokine	Major producer	Effect
IL-4/IL-13	T cells	Alternate Mϕ activation
		↑ MHCII, B7-1, B7-2
		↑ giant cell formation
		↓ IL-1, TNF-α, IL-6, IL-12
IL-10	Mϕ	Mϕ deactivation
	DC	↓ IL-1, TNF-α, IL-6, IL-12
	Activated T and B cells	↓ MHCII, B7-1, B7-2
IL-12	Mϕ	T-cell proliferation
	DC	$CD4^+$ Th1 differentiation
	Others	↑ IFN-γ
		↑ CTL activity
IFNγ	T cells	Mϕ and PMN activation
	NK cells	$CD4^+$ Th1 differentiation
		B-cell isotype switching (IgG2a, IgG3)
		↑ NK cell cytolytic activity
		↑ vascular adhesion molecules
		↑ MHCI and MHCII
		↑ TNF-α, IL-1, IL-12, IFN-β
		↓ IL-10
IL-18	Mϕ	T-cell proliferation
		$CD4^+$ Th1 differentiation
		↑ IFNγ
		↓ IL-10
IFN-α/β	Mϕ	Mϕ and NK activation
	Others	↑ CTL activity
		↑ MHCI
TNF-α	Mϕ	Mϕ and PMN activation
	Others	Inflammatory cell recruitment
		↑ vascular adhesion molecules
		↑ MHCI
		↑ acute phase proteins
		↑ T-cell apoptosis
TGF-β	Platelets	Monocyte activation
	Mϕ	Mϕ deactivation
		↑ extracellular matrix proteins
		↑ selected growth factors

CTL, cytotoxic T lymphocyte; DC, dendritic cell; Th1, T-helper cell 1; IFN, interferon; IgG, immunoglobulin G; IL, interleukin; PMN, polymorphonuclear neutrophil; MHC, major histocompatibility complex; Mϕ, macrophage; NK, natural killer; TGF, transforming growth factor; TNF, tumor necrosis factor.

mediates and regulates many local and systemic immune functions. Cytokines bind to their cognate cell surface receptors and signal through a variety of pathways, including the Janus-family kinase (Jaks) and signal transducer and activator of transcription (Stat) proteins (Imada and Leonard 2000). The properties and characteristics of a few selected cytokines are listed in Table 2. Many of those listed are involved in macrophage activation (IL-4, IL-13, IL-12, IL-18, and IFN-γ) or deactivation (IL-10 and TGF-β). Cytokines, such as TGF-β, also play an important role in the suppression and resolution of the immune response (Ashcroft 1999).

Chemokines, or chemotactic cytokines, are small, structurally related peptides that are recognized by seven transmembrane G-protein-coupled receptors on their target cells (Thomson 1998). They are involved in a variety of homeostatic functions, including organogenesis and hemopoiesis, but also function to recruit neutrophils, monocytes, immature dendritic cells, and activated T cells to the sites of infection (Olson and Ley 2002). Chemokines are highly basic proteins and can bind to glycosaminoglycans on extracellular matrix surfaces, generating gradients that attract leukocytes and promote their attachment and diapedesis through vascular endothelium, as described above. Chemokines are divided into four families, based on the number and position of conserved cysteines: C, CC, CXC, and the CX3C chemokines. In general, CXC chemokines, such as IL-8, attract neutrophils, whereas CC and C chemokines, such as monocytic chemotactic peptide 1 (MCP-1)

and lymphotactin, attract monocytes and lymphocytes. Chemokines can also induce the release of proinflammatory mediators and stimulate the respiratory burst.

ANTIGEN PRESENTATION

Antigen presentation, along with cytokine production, is a critical component of innate immunity required for the generation of the adaptive immune response and resolution of most infections (Fearon and Locksley 1996). Mϕs present antigens only to primed T cells, whereas DCs have the ability to prime naïve T cells (Mellman and Steinman 2001). Antigen presentation results in the generation of pathogen-specific immunity and specific subsets of T cells. These subsets include the $CD4^+$ T cells, which are involved in the resolution of intracellular (T-helper (Th) 1 cells) and extracellular (Th2 cells) pathogens, and $CD8^+$ T cells, which are involved in killing cells infected with cytosolic pathogens. Both $CD4^+$ and $CD8^+$ T cells can activate the antimicrobial activities of Mϕs, although $CD4^+$ Th2 cells normally mediate Mϕ-independent responses to extracellular parasites, such as helminths.

Antigen presentation requires the noncovalent association of the antigen with MHC molecules. This association occurs via two main routes, through loading of antigens onto MHCII, which have been ingested and degraded in the lysosomes, and loading of antigens onto MHCI, which are derived from the cytosol. This is an oversimplified scheme, however, because lysosomally derived antigens can be loaded on MHCI molecules, although the mechanisms involved are less clear. Antigens loaded onto MHC molecules are normally peptides, but lipids and glycolipids can be presented through MHC-like molecules to T cells. We describe the various cellular mechanisms in antigen loading and presentation to T cells, including a brief description of the co-stimulatory molecules and cytokines involved.

MHCI is expressed by nearly all cells and presents cytosolic peptides to cytotoxic $CD8^+$ T cells (Guermonprez et al. 2002). These peptides are generated by the proteasome and are translocated into the ER by transporter associated with antigen processing (TAP) protein where they associate with the MHCI molecules before transport to the cell surface. As the presented peptides originate from the cytosol, MHCI presentation is important in the control of cytosolic pathogens, such as viruses.

MHCII is expressed by Mϕs, DCs, and B cells and presents exogenously derived peptides to $CD4^+$ T-helper cells (Guermonprez et al. 2002). MHCII is upregulated after activation of Mϕs and on maturation of DCs. Exogenous antigens released from the degradative late endosomal and/or phagosomal compartments are thought to be loaded onto MHCII in the MIIC compartment. MHCII molecules are associated with an invariant chain (Ii), which prevents association with endogenous peptides during synthesis in the ER and Golgi body. Ii is removed by proteolysis and the actions of an auxiliary molecule, HLA-DM, in the MIIC compartment, allowing the binding of foreign peptide and transport to the cell surface. In certain circumstances peptides can be also be loaded onto MHCII in the ER, early endosomes, and at the plasma membrane (Robinson and Delvig 2002). As peptides derived from the endosomal/phagosomal pathway are presented through MHCII, this presentation pathway is, however, critical for the control of intracellular pathogens.

Antigen can also be presented to T cells through two other classes of molecules: MHCIb and CD1 (Porcelli and Modlin 1999; Schaible et al. 1999). MHCIb present short *N*-formylmethionine-containing peptides of bacterial and/or mitochondrial origin to $CD8^+$ T cells. Although MHCIb is structurally similar to MHCIc, the processing and peptide-loading mechanisms are unclear and may be TAP independent. Also structurally related to MHCI is the CD1 family of proteins, consisting of five members, four of which (CD1a, -b, -c, -e) are found only in humans. Most of these proteins, expressed mainly by activated Mϕs, DCs, and B cells, are capable of presenting microbial lipid and glycolipid antigens, such as mycolic acids from mycobacteria, to cytotoxic $CD4^-$ $CD8^-$ T cells and possibly also $CD8^+$ T cells. Antigen loading is TAP independent.

In addition to T-cell receptor (TCR) recognition of antigen presented on MHC molecules, the activation and proliferation of T cells requires a 'second' signal (Guermonprez et al. 2002). This additional signal is mediated by co-stimulatory molecules on the APCs, including CD40, B7-1, and B7-2 which interact with CD40L, CD28, and CTLA4 on the lymphocytes. These interactions activate the APCs and mediate the type of $CD4^+$ T-helper cell (Th1 or Th2) produced.

The differentiation of $CD4^+$ T cells into Th1- or Th2-type cells is also mediated by cytokines. Activation of DCs in the periphery and crosslinking of CD40 during the presentation of antigens induce IL-12 production, which biases the development of naïve T cells to the Th1 type, suppressing the production of Th2-type cells. Conversely, IL-4 stimulates the production of Th2-type cells, while suppressing Th1-type development. The driving factors behind Th2 development are still unknown, leading some investigators to propose that Th2 is the default pathway. The role and generation of Th1 and Th2 T cells in infection are discussed in greater detail in later chapters.

Macrophages and other APCs have the ability to ingest apoptotic or necrotic cells and present the antigens they contain in a process known as cross-presentation, or crosspriming (Heath and Carbone 2001). These antigens can be presented on both MHCI and MHCII molecules by a process that is influenced by

several factors in vivo, including antigen dose, age of the host, and tissue type. It should be noted that cross-presentation of cellular antigens can also lead to T-cell tolerance (cross-tolerance).

SUBVERSION OF MACROPHAGE FUNCTION BY PATHOGENS

Although Mϕs are very efficient at recognizing and destroying microbes, pathogens have evolved numerous strategies to avoid or subvert the antimicrobial functions of these leukocytes. Pathogens can evade or promote recognition through specific PRRs, and they can block or modify the phagocytic pathway, the antimicrobial mechanisms, the production of soluble mediators, and the ability of Mϕs to present antigens. Studies of these microbial subversion strategies have, however, greatly aided our understanding of the basic mechanisms underlying the cellular processes in Mϕs and other leukocytes.

Pathogens have developed mechanisms to avoid phagocytosis or to direct phagocytosis through specific receptors. Phagocytosis mediated by FcγR, but not CR3, for example, results in the production of proinflammatory mediators and induces the respiratory burst (Underhill and Ozinsky 2002). Consequently, CRs are commonly used by intracellular pathogens, such as *Mycobacterium tuberculosis*, to gain access to host cells (Ernst 1998). Pathogens may induce entry into macrophages, such as salmonellae, which stimulate macropinocytosis by transferring proteins into the host cytosol using a type III secretion system (Goosney et al. 1999). Other pathogens actively block phagocytosis, such as *Yersinia* which use a type III secretion system to transfer proteins to block the signaling mechanisms that control cytoskeletal rearrangements (Fallman et al. 1995; Cornelis 2002).

Macrophages also provide numerous niches for intracellular pathogens, which have evolved a variety of mechanisms for survival within these cells. Some pathogens interfere with phagosomal maturation, such as *Mycobacterium tuberculosis*, which arrests maturation at an early stage (Armstrong and Hart 1971). Pathogens such as *Legionella*, are able to convert the phagosome to a unique vacuole, whereas others, such as *Shigella* spp., escape the phagosome completely and reside in the host cytosol (Portnoy et al. 1988; High et al. 1992). Some pathogens, such as *Leishmania* and *Coxiella* spp., have even adapted to life within the harsh environment of the phagolysome (Chang and Dwyer 1976; Heinzen et al. 1996; Rabinovitch and Veras 1996).

The antimicrobial mechanisms of Mϕs present other obstacles that have been overcome by pathogens, leading to the development of a number of resistance mechanisms. Pathogens overcome the acidification of the phagosome by excluding the vesicular proton pump ATPase, such as occurs with mycobacteria, or escape into the cytoplasm, as mentioned above (Sturgill-Koszycki et al. 1994). Essential nutrients can be acquired by, for example, secreting siderophores, which bind iron with a higher affinity than host molecules, such as the mycobactins and exochelins of mycobacteria (De Voss et al. 1999). The respiratory burst can be avoided by entry through specific receptors, as discussed, but it can also be suppressed by inhibiting the activation cascades, as occurs with *Yersinia* spp. (Cornelis 2002). Microbes, such as salmonellae and mycobacteria, protect themselves from toxic oxidants and reactive nitrogen intermediates by producing enzymes, such as catalase, glutathione reductase, alkyl hydroperoxide reductase, and superoxide dismutase, which break down these compounds (Storz et al. 1990; Manca et al. 1999).

Pathogens are able to modulate the ability of Mϕs to interact with the rest of the immune system, by affecting their ability to produce cytokines and to present antigens. Pathogens such as the pox and herpes viruses produce virokines and viroceptors, which mimic cytokines and cytokine receptors, whereas pathogens such as mycobacteria can deactivate Mϕs, making them refractory to activating cytokines, and induce the production of the anti-inflammatory cytokine, TGF-β (McFadden et al. 1998; Mosser and Karp 1999). Viruses and bacteria have also been shown to prevent surface expression of both MHCI and MHCII, or they can produce super-antigens that can cause extensive nonspecific T-cell activation (Herman et al. 1991; Schaible et al. 1999; Yewdell and Bennink 1999; Papageorgiou and Acharya 2000). Thus, pathogens have not only evolved mechanisms to subvert Mϕ function, they have also evolved mechanisms to modulate the entire immune response.

ROLE OF MACROPHAGES IN HOMEOSTASIS

Macrophages, as a system, display features consistent with a major role in tissue homeostasis. They are constitutively dispersed throughout the body, in the absence of inflammation, and can be recruited in increased numbers to sites of local injury and infection. They are relatively long-lived cells, remaining biosynthetically active, display a range of plasma membrane receptors for recognition of endogenous and exogenous ligands, and are able to secrete a wide variety of products in response to stimulation. Through these activities they regulate the activity of many cell types in their local microenvironment, as well as systemically. Here we touch briefly on selected aspects to illustrate diverse homeostatic aspects of Mϕ function particularly relevant to infection.

As discussed above, resident tissue Mϕs show great variation, the functions of which are not well understood, but can be broadly interpreted as homeostatic. In bone marrow, for example, stromal Mϕs play a tropic role in hemopoiesis by interacting with developing myeloid and erythroid cells (as well as removing

erythrocyte nuclei) (Crocker et al. 1991). In lung, alveolar Mϕs contribute to surfactant metabolism as well as host defense. In the central nervous system, microglia persist throughout adult life, closely associated with neurons and astrocytes, possibly contributing to neurotransmitter catabolism (Perry et al. 1993).

Macrophages play a major role in the uptake and destruction of apoptotic, senescent, and necrotic cells, through a range of scavenger and other receptors (Fadok et al. 2001; Peiser et al. 2002). Apart from their phagocytic and surface immune interaction molecules such as MHC and co-stimulatory antigens, Mϕs are well placed to remove a wide range of ligands from the circulation, or extravascular tissue fluids by phagocytosis and endocytosis. Examples include classic reticuloendothelial cell clearance functions of Kupffer cells, often shared with liver sinusoidal, true endothelial cells. Thus many lysosomal hydrolases express a terminal saccharide recognized by the Mϕ mannosyl/fucosyl receptor (East and Isacke 2002). Other important host-protective endocytic clearance systems include CD91 (α_2-macroglobulin–protease complexes) and CD163 (haptoglobin–hemoglobin complexes) (Binder et al. 2001; Kristiansen et al. 2001). The products of activated neutrophils can also be removed by several of the above receptors.

Macrophages express a variety of constitutive and inducible metabolic activities that help to catabolize substrates such as hemoglobin, and inactivate chemical compounds including drugs. Mϕs contribute to bile pigment formation through hemoxygenase and other enzymes, and can express high levels of cytochrome P450. They contribute to iron homeostasis through a variety of pathways.

MACROPHAGE-INDUCED PATHOLOGY

Many of the properties of Mϕs, described above, can be readily extrapolated to pathological responses to infection and metabolic diseases in which Mϕs play a central role, with or without contributions from other cells (Gordon 1999, 2001, 2003b). We illustrate the range of diseases by selected examples, in which Mϕs are overactive or deficient in function. These include chronic infections and/or inflammatory diseases, such as tuberculosis and rheumatoid arthritis in which Th1 responses and TNF-α production predominate, and a range of storage diseases, such as atherosclerosis.

Granuloma development is a characteristic of mycobacterial infection. Persistence of a microbial stimulus, in Mϕs themselves, can result in the focal accumulation of newly recruited monocytes and their differentiation into Mϕs (epithelioid and Langhans' giant cells), together with T lymphocytes, other myeloid cells, and fibroblasts. The granuloma Mϕs express a range of cell activation markers including lysozyme and proinflammatory cytokines (TNF-α, IL-1β, IL-6), as well as IL-10. TNF-α is essential for granuloma formation, as shown in anti-

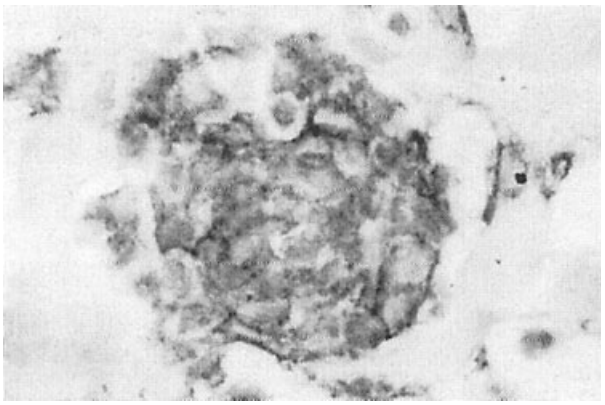

Figure 4 C. parvum-*induced granuloma in the liver stained with F4/80. The majority of the cells in the granuloma stain positive for F4/80, as do some adjacent Kupffer cells.*

body and genetic depletion studies. The type 3 complement receptor is also important in mobilization of monocytes to form granulomas. A granuloma stained with F4/80 is shown in Figure 4.

The immunologically primed host is exquisitely sensitive to LPS or microbial stimuli, which readily precipitate a septic shock syndrome, mediated through CD14 and TLR pathways, with diffuse intravascular coagulation and vascular collapse, mainly through the actions of cytokines such as TNF-α and IL-1β on the endothelium. Infection by a range of other intracellular pathogens mentioned above can give rise to widespread local and systemic inflammatory sequelae, including wasting, fibrosis, and secondary amyloidosis, as well as immunosuppression.

Other types of modified chronic inflammation in which Mϕs are prominent include atherosclerosis and, perhaps, Alzheimer's disease. Accumulation of intra- or extracellular lipoprotein or fibrillar deposits in large arteries or brain, respectively, results in persistent Mϕ secretion of tropic and destructive products. Classic Mϕ storage diseases include lysosomal storage of macromolecules caused by genetic enzyme deficiency and iron overload. Such Mϕs can become potent secretory sources of enzymes that serve as markers (e.g. chitotriosidase in Gaucher's disease), or mediators of tissue injury (elastase, collagenase).

Deficiencies of Mϕ function include failure to clear apoptotic cells, which may contribute to autoantigen formation in diseases such as systemic lupus erythematosus, and the inability to destroy opportunistic pathogens in AIDS. Rare inherited deficiencies of respiratory burst components result in inefficient killing of a range of microorganisms, in chronic granulomatous disease.

CONCLUSION

We have briefly highlighted the various roles that Mϕs play in anti-infectious immunity and have shown that,

through their ability to recognize, ingest, and destroy microbes, as well as recruit other immune cells to the sites of infection, Mϕs are key cells in innate immunity. We have demonstrated that Mϕs play an essential role in specific immunity by modulating this response through the release of cytokines, and other soluble mediators, and acting as effector cells and accessory cells in secondary lymphocyte activation. Although macrophages are essential for the control of infection, we have also noted some of their homeostatic functions and their ability to induce pathology.

INTRODUCTION

The importance of neutrophils in host defense is best demonstrated in hereditary and acquired neutropenias, conditions that place an individual at risk of life-threatening infections. Neutrophils devote their activity mainly to producing oxygen-reactive species, which combine with granule constituents to form very potent microbicidal systems. This was first appreciated in the late 1950s when it was discovered that respiration was not dependent on mitochondria. Through the combined efforts of a number of independent investigators, not only was the identification of the release of hydrogen peroxide and superoxide discovered as a major feature of the cell (Paul and Sbarra 1968; Babior et al. 1973), but also the special location of the unassembled and assembled components of the oxidase were described (reviewed by Heyworth et al. 1999). A much more comprehensive understanding of the biochemistry of the oxidase came through the efforts of Segal and colleagues (1978), who identified a *b*-type cytochrome which formed a key component of the oxidase system of the cell and which was found to be the defect in some patients who had chronic granulomatous disease (CGD) whose cells failed to generate oxygen radicals and kill some bacteria. Subsequently, the complexity of the oxidase became evident with the identification of several different components that exist in a dormant form until phosphorylated and assembled at the phagosome membrane. The understanding of the generation of antimicrobial substances by neutrophils was further extended by the work of Klebanoff (1968), who demonstrated the reaction of the azurophilic granule enzyme, myeloperoxidase (MPO), with H_2O_2 and chloride to yield hypochlorous acid.

During this time, excitement about the characteristics of the respiratory burst of neutrophils overshadowed many other important discoveries such as the identification of antimicrobial cationic proteins in granules by Zeya and Spitznagel (1966), and it was not until the 1990s, when Lehrer and Ganz (1990) purified these as defensins, that major interest developed.

The discovery in the late 1970s and early 1980s of the role of specific colony-stimulating factors (CSFs) in the regulation of neutrophil hemopoiesis through the efforts of Metcalf and colleagues (Metcalf 1989) opened new vistas in granulocyte biology with potential therapeutic applications in neutrophil disorders.

In the 1980s, the author's group and others discovered more intriguing properties of this cell, that of priming. In this process, the neutrophil interacts with cytokines such as tumor necrosis factor (TNF) and gains significantly greater antimicrobial powers (Ferrante and Mocatta 1984; Klebanoff et al. 1986). Thus it became evident for the first time that the neutrophil can be educated by factors released by tissues, endothelial cells,

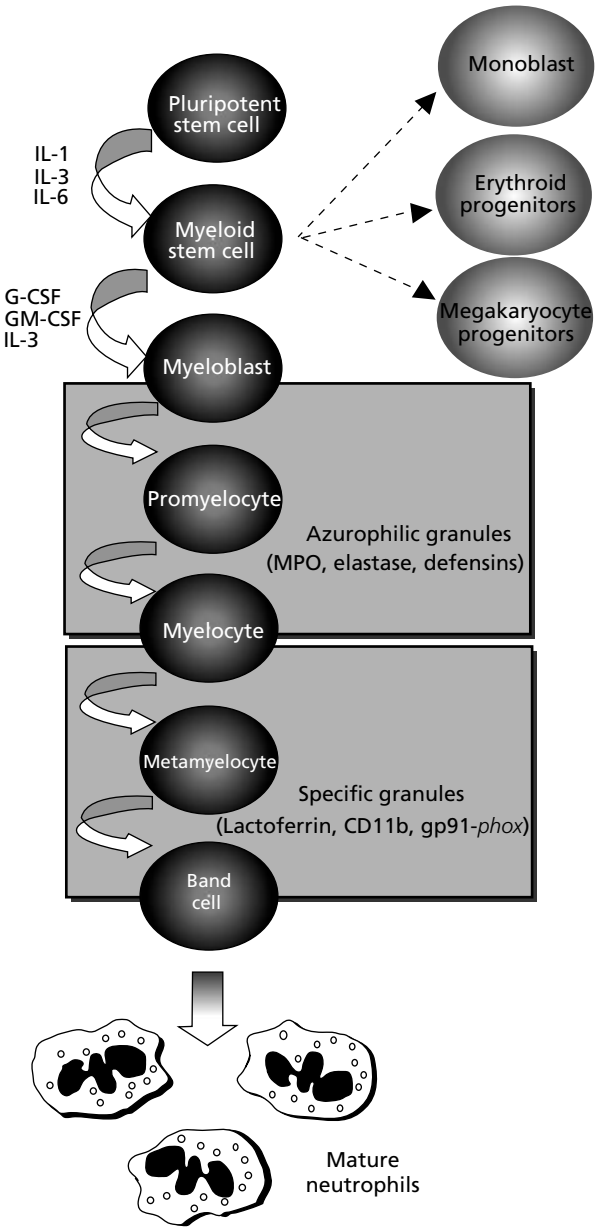

Figure 1 *Scheme showing the different stages of neutrophil development in the bone marrow from stem cells. Cytokines that promote granulocyte development are outlined. Note the initial appearance of azurophilic granules and later expression of specific granules. Some of the markers specific for the different granules are also shown.*

lymphocytes and monocytes in the way that macrophages were shown to be activated by interferon-γ in the 1970s.

When Tiku et al. (1986) reported that zymosan-stimulated neutrophils released interleukin (IL) 1 (IL-1), it was appreciated that neutrophils were able to promote the immunological response through the release of cytokines that regulate macrophage and lymphocyte function.

The ability of neutrophils to migrate rapidly into tissue at infection sites, release oxygen reactive species, and degranulate in order to kill bacteria needs to be regulated because of their tissue-damaging properties. The discovery that neutrophils die by programmed cell death (apoptosis), which protects against tissue damage mediated by this cell, has contributed significantly to our understanding of the mechanism of regulation of the inflammatory reaction.

The concept of neutrophil emigration from blood to tissues under a gradient of molecules had already been put in place in the mid- to late 1800s by the founding fathers, such as Metchnikoff (1893). Since then, substantial complexity has been added to this concept. This includes the array of the chemotactic factors generated during inflammation, the mechanisms of cell movement, and the interactions required between neutrophils and the endothelium for emigration into tissues.

Although the neutrophil has always been considered the 'poor cousin' of the mononuclear phagocyte because of its short life and inability to be educated to perform many of the intricate functions of the macrophage necessary to develop a strong immunological defense system, it is evident that singular properties of the neutrophil are becoming apparent. This chapter covers the properties of neutrophils in general and attempts not only to describe properties that are considered classic from the times of Elie Metchnikoff, but also to illustrate those properties that have only recently been appreciated.

NEUTROPHIL DEVELOPMENT

The bone marrow is involved in the production of neutrophils. This is the site for proliferation of neutrophil precursors and maturation to the mature stage (Figure 1) (Bainton 1999). Once cells evolve from pluripotent stem cells to progenitor cells, they can no longer differentiate into any type of blood cell and will differentiate into the mature cells. Hemopoiesis is regulated by a number of cytokines. Four of these, the CSFs, IL-3 (multi-CSF), macrophage (M)-CSF, granulocyte–macrophage (GM)-CSF, and G-CSF regulate development of leukocytes (Metcalf 1989). The granulocyte lineages come under the control of G-CSF, GM-CSF, and IL-3. These factors regulate the production of neutrophils.

During neutrophil development in the bone marrow, at different stages the cell acquires functional properties necessary for optimal antimicrobial activity (Figure 1) (Borregaard and Cowland 1997). As constituents of granules such as MPO and eventually lactoferrin are synthesized, they are packaged in their respective granules. Components of the oxidase, such as the gp91^{phox} and functional surface receptors (CD18, CD11b) which ligate complement-opsonized bacteria, also become expressed at the plasma membrane of these cells as the cells differentiate toward the mature neutrophil. The granules to appear first are the azurophilic (primary) granules containing MPO and elastase, morphologically

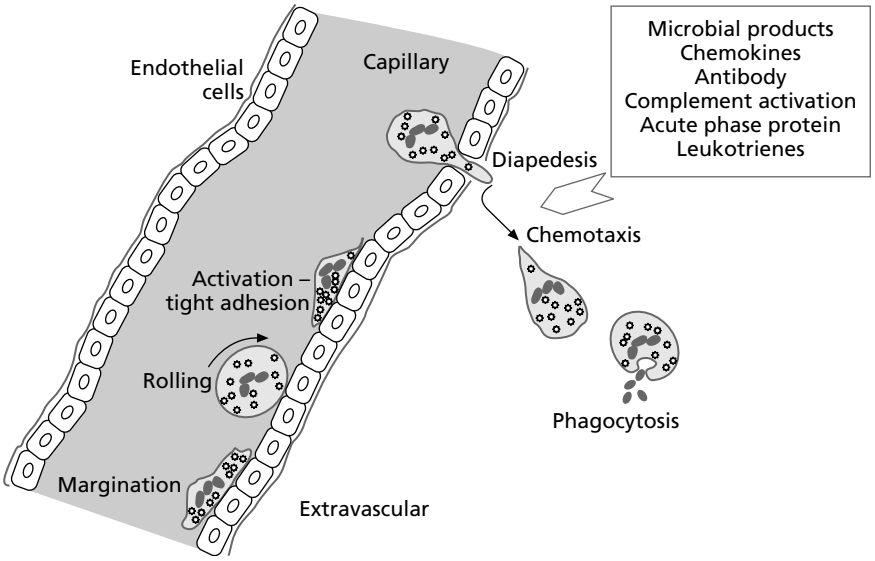

Figure 2 *Diagrammatic representation of early events in the recruitment of neutrophils to inflammatory sites. Stimulation of both neutrophils and the endothelium will promote the process of rolling, attachment, and transendothelial cell migration. The nature of the inflammatory response and mediators produced dictates a preference for selective recruitment of neutrophils at the level of neutrophil receptors for promoting adhesion and chemotaxis and, also, endothelial cell activation.*

seen at the promyelocyte stage. The secondary granules (specific) characterize the myelocyte stage. Once the cell lineages reach the metamyelocyte stage, the cells cease to divide.

MOBILIZATION TO SITES OF INFECTION AND DAMAGED TISSUES

Accumulation of neutrophils at infection foci and sites of tissue damage begins with margination, whereby the neutrophils attach to the capillary wall and have the potential to migrate out of the blood vessel (Gallin and Snyderman 1999) (Figure 2). This is followed by diapedesis, a step in which the cells squeeze through gaps in the endothelial cell layer. Their chemotactic properties enable the cells to migrate preferentially towards the source of infection and local tissue damage, and may experience migration inhibition to enable retention of cells at the infection site.

To achieve cell accumulation in tissues, a number of complex interactions occur between receptors on neutrophil surfaces and various soluble or cell surface ligands, which stimulate the cells to respond (Gallin and Snyderman 1999). Bacterial infiltration of tissues leads to the release of microbial products (e.g. lipopolysaccharide (LPS)), which can promote neutrophil accumulation in tissues themselves, via their ability to activate the endothelium and/or act as chemotactic factors. These microbial products and structures can also promote the generation of chemotactic active peptides of complement such as C5a and stimulate tissues to produce chemokines (cytokines such as IL-8) and the leukotriene, LTB_4, a chemotactic factor produced during the metabolism of arachidonic acid via the lipoxygenase pathway. Some cytokines such as TNF can also cause migration inhibition, especially at concentrations likely to be generated at inflammatory sites (Ferrante 1992).

Although many of the properties of the mediator effects on cells are reasonably well understood, how the network of interactions coordinately brings about a physiological response and when this response becomes uncontrolled to give rise to pathophysiology are far from clear and continue to be an area of research interest.

The cell cytoskeleton

The intracellular components are embedded in a supporting frame, the cytoskeleton, which consists of microfilaments, microtubules, intermediate filaments, and the microtrabecular lattice. Second messengers link the surface ligand-binding receptor to the cytoskeleton. Changes in this cytoskeleton then form the basis for cell movement, phagocytosis, granule movement, receptor recycling, and activation of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (Edwards 1994; Stossel 1999).

Microfilaments found predominantly beneath the plasma membrane are considered to be the most dynamic of the components of the cytoskeleton. Microfilaments are composed of actin molecules that exist as monomers (G-actin), which can reversibly assemble into actin filament (F-actin). Actin polymerization is initiated by the activation of actin monomers by divalent cations. A range of actin-binding proteins is involved in maintaining actin in an unpolymerized state in cells and promoting rapid assembly during cell activation. Microtubules consist of α- and β-tubulin subunits arranged in a

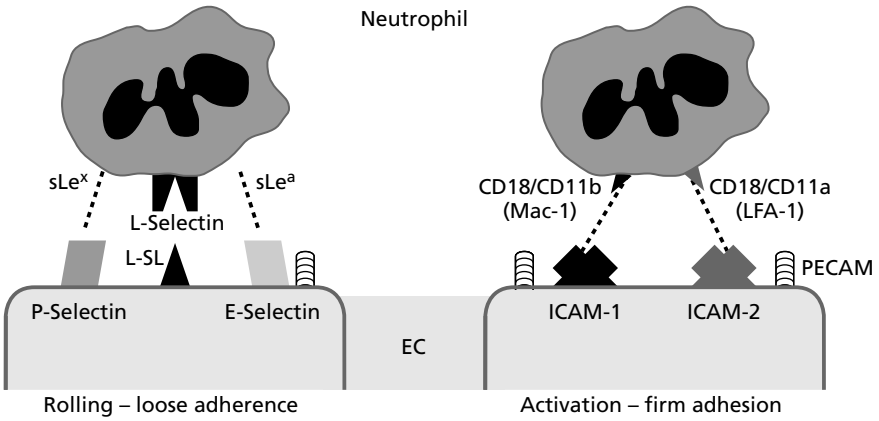

Figure 3 *The receptor ligand involved in the interaction of neutrophils with endothelial cells. Interaction of the tetrasaccharides sialyl Lewis^a (sLe^a), sLe^x, L-selectin with the counter-receptor/ligand, E-selectin, P-selectin, and L-selectin ligand (L-SL) promotes loose adherence and enables the neutrophils to roll. Endothelial cell (EC) activation induces/upregulates expression of cell adhesion molecules, ICAM-1/-2 enabling interactions with β_2-integrins and promoting firm adhesion of the cell to the endothelial surface. PECAM then facilitates transendothelial cell migration.*

helical structure. Assembly of these is increased during cell activation. Assembly is upregulated by cyclic guanosine monophosphate (cGMP) and decreased by cyclic adenosine monophosphate (cAMP) and Ca^{2+}. Neutrophils also have intermediate filaments, which consist of vimentin molecules that can be rapidly polymerized. Their function is not clearly known but they may be involved in connecting the peripheral region of the cell to the central regions. The microtrabecular lattice, an intricate network of fine strands, is also part of the cytoskeleton. Actin is the major polypeptide of this lattice. Cytoplasmic granules can be found associated within this lattice.

Neutrophil–endothelial cell interactions

Recruitment of neutrophils to sites of inflammation requires a series of events involving rolling, activation, adhesion, and transendothelial cell migration, which are depicted in Figure 2 and 3. The type of inflammation may dictate the cell types that leave the circulation and migrate into tissues which is in part a reflection of the type of adhesion molecules upregulated, i.e. members of the common cell adhesion molecule (CAM) family, apart from their selection by specific chemokines.

The events seen at inflammatory sites are the emigration of neutrophils from the circulation in the postcapillary venules and their loose and reversible adhesion to the endothelial cells (see Figure 2). This interaction, which mainly involves the selectin family and the sialylated Lewis-bearing ligands (see Figure 3), enables the cells to roll under the influence of forces of blood flow (Robinson et al. 1999). This interaction leads to neutrophil activation as such and indirectly by mediators released by the endothelial cells. Integrins are upregulated to high-affinity states, rolling ceases, and the cells show tight binding to the endothelium through the counter-receptor, intercellular adhesion molecule (ICAM)-1, and ICAM-2 (members of the immunoglobulin gene superfamily) (see Figure 3) (Kishimoto et al. 1999).

The neutrophils advance to crawl/squeeze between the endothelial cell junctions in an amoeboidal manner (Muller 1999). This transendothelial cell migration is highly dependent on platelet endothelial cell adhesion molecule-1 (PECAM-1). Having traversed the intercellular junctions, neutrophils need to migrate across the basal lamina. This again involves recognition molecules such as PECAM-1 and either physical penetration or degradation of the matrix by release of proteases.

Chemotaxis

Neutrophils are quick to respond to a gradient of chemical agents generated at a site of infection and tissue damage. These chemotactic agents bind to receptors on the cell surface to bring about a network of interactions that promotes directional movement of the cell toward the source of the chemical agent (Uhing and Snyderman 1999). This involves the recognition of a concentration gradient spanning the front and rear ends of the cell, and a combination of calcium mobilization, actin, actin-binding proteins, and proteins that regulate the cytoskeleton of the cell.

After the binding of chemotactic agents to neutrophils, the cell undergoes a shape change, characteristically bipolar. The leading edge of the cell orients toward the source of chemotactic factor and forms a pseudopod or lamellapodium that adheres to the substratum. Toward the rear of the cell can be found the nucleus and the contractile uropod exhibiting retraction fibers, which enable the cell to adhere. A repeated sequence of lamellapodia extension towards the chemo-

tactic source and uropod retraction towards the cell body leads to cell migration.

RECOGNITION AND PHAGOCYTOSIS OF MICROBIAL PATHOGENS

Innate immunity in vertebrates expresses primitive forms of recognition system that involve recognition of structures generally based on their charge and special arrangement of chemical groups (Gallin and Snyderman 1999). These possibly evolved from scavenger properties of primitive cells such as amoebae. Thus carbohydrate residues on the surface of a pathogen may be recognized by receptors that perform scavenger functions. These types of recognition system may play an important role at sites in which complement and antibody levels are very low or absent.

Neutrophils display a wide range of receptors on their surface, which enable a highly regulated attack on microorganisms, although such receptors will also direct the neutrophil attack toward damaged tissue. Several well-characterized receptors are outlined in Table 1. These receptors are set into operation when bacteria are opsonized with antibody and/or complement components (Greenberg 1999), enabling neutrophils to attach to the bacteria via the Fc portion of the immunoglobulin molecule involving FcγR or FcαR. Deposition of complement components on the surface of bacteria leads to binding of neutrophils to bacteria via the complement receptors, CR1, CR3, and CR4. The ligation of these receptors promotes the phagocytosis of the microorganisms and their killing by stimulating the neutrophil respiratory burst and degranulation.

The binding of antibody to the surface antigens of microbial pathogens leads to the exposure of a region in the Fc domain of the immunoglobulin molecule, which can be recognized by the Fc receptors (FcRs) on the neutrophil. There are three types of FcγR on neutrophils recognized to date: FcγRI (CD64), FcγRIIA (CD32), and FcγRIIIB (CD16). The function of these is to recognize the Fc domain of IgG, but their ability to do this is dependent on various physiological and pathophysiological conditions. The FcγRI is a glycosylated 72-kDa transmembrane protein which is absent in blood neutrophils but is upregulated and detected following pre-exposure to interferon-γ (IFN-γ) which involves transcription. This contrasts with the regulation of FcγRIIIB, which can be upregulated by release from granules and downregulated by shedding. The FcγRI, in comparison to FcγRIIA and FcγRIIIB binds monomeric IgG with high affinity.

Table 1 *Functional receptors mediating phagocytosis of opsonized particles and activation in neutrophils*

Receptor type	Ligand
FcγRI (CD64)[a]	Fc domain of IgG
FcγRIIA (CD32)	Fc domain of IgG
FcγRIII B (CD16)	Fc domain of IgG
FcαR (CD89)	Fc domain of IgA
CR1 (CD35)	C3b
CR3 (CD11b/CD18)	C3bi
CR4 (CD11c/CD18)	C3bi

a) CD classification of Fcγ and CR on neutrophils.

The significance of FcγRI on neutrophils is not clear because it is expressed by neutrophils only after long-term exposure to IFN-γ. However, this may argue for an important role for neutrophil activation and priming in a similar manner to mononuclear phagocytes (Ferrante 1992). Similarly, the role of FcγRIIIB in neutrophils is not clear because it lacks a transmembrane or cytoplasmic domain, suggesting that it is not involved in intracellular signaling for a respiratory burst and/or degranulation. But, because it is expressed in abundance on neutrophils, its main function may be the binding and removal of immune complexes. Presumably FcγRIIIB promotes the binding of bacteria but it needs to cooperate with FcγRIIA to stimulate the relevant intracellular signals.

FcαR which recognizes the Fc domain of IgA is also expressed by neutrophils. IgA in high concentration opsonizes and facilitates microbial phagocytosis and activation of the neutrophil respiratory burst through this receptor. This is likely to be an important defense mechanism in mucosal surfaces where the complement concentration is likely to be too low to promote phagocytosis.

During inflammation, whether induced by microbial pathogens or altered tissues, complement is activated in a cascade manner to generate components that are recognized by neutrophils, some of which act as opsonins to promote phagocytosis. The component C3 is of vital importance because it generates fragments, C3b and C3bi, which when deposited on bacteria facilitate recognition by neutrophils usually through the receptors CR1, CR3, and CR4 (Greenberg 1999) (see Complement). Whether particles are coated with C3b or C3bi is dependent on whether complement is activated via the classic or the alternate pathway. CR1 (LAF-1) binds C3b primarily and has very weak affinity for C3bi. In contrast CR3 (Mac-1) binds to C3bi deposited on bacteria with very high affinity. CR4 also probably recognizes C3bi. Neutrophils can recognize microbial surfaces in the absence of antibody and complement by an opsonin-independent system that may involve CR3 receptors recognizing other residues.

Appropriate recognition and adherence of neutrophils to bacteria and fungi lead to the engulfment of these microbes, thereby confining and limiting their harmful effects. This involves the formation of a pseudopod, which extends around the surface of the bacteria in a 'zipper hypothesis' manner to confine the organisms within a vacuole. The cell is then able to deal with the engulfed bacteria by a combination of pH changes in the

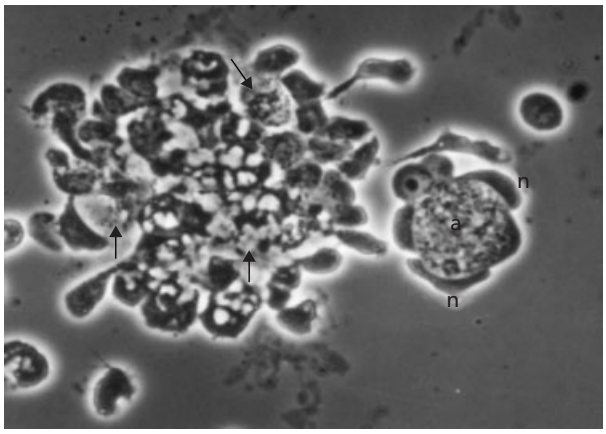

Figure 4 *The interaction of neutrophils with pathogenic free-living amoebae in the peritoneal cavity of mice immune to* Naegleria fowleri. *Mice were injected intraperitoneally with living amoebae and, after 8 h, the peritoneal content harvested and examined. phagocytic vacuole and the release of toxic oxygen intermediates and granule constituents, some of which have enzymatic properties. A unique interaction between neutrophils and parasites has been described in which the neutrophil extracts *Plasmodium falciparum* from within an erythrocyte without lysis of the erythrocyte (Kumaratilake et al. 1994).

Frustrated phagocytosis has been found to occur when a particle is too large to be engulfed by the neutrophil. This may occur with some large unicellular protozoan parasites such as amoebae (Figure 4) and in the case of multicellular parasites and hyphae of *Candida albicans*. Interaction with altered tissues may also lead to an event of frustrated phagocytosis. In these situations, a 'partial vacuole' is formed in which the environment seen in a complete phagocytic vacuole is created. The reactive oxygen species and granule constituents are released and able to damage and lyse the cells. Usually a number of neutrophils will attack one multicellular parasite and presumably it is the net effect of surface parasite damage induced by several neutrophils that leads to parasite death. In autoimmune diseases such as glomerulonephritis and rheumatoid arthritis, the antigen–antibody complexes deposited on the membranes and their ability to activate complement promote this neutrophil-mediated cellular cytotoxicity.

ANTIMICROBIAL ARMORY OF THE NEUTROPHIL

Once neutrophils localize at an infection site and come into contact with bacteria, the cells are stimulated to produce an array of microbicidal substances within seconds and minutes. The neutrophil microbicidal systems can be divided into the nonoxidative and oxidative components. Depending on the type of bacteria or parasite, either one of these components may be effective or, in other cases, both systems are seen to operate synergistically.

Nonoxidative antimicrobial systems

Neutrophils contain two major granules, specific and azurophilic granules which can be distinguished by the presence of different constituents (Table 2). The constituents present in the azurophilic granules have primarily an antimicrobial function. The ability of these constituents to kill microbial pathogens contrasts with a mechanism by which organisms can be killed in their absence, simply by being confined in a phagocytic vacuole and destroyed by the microbe's own products. Evidence for a role of nonoxidative mechanisms in neutrophil-mediated microbial killing is seen from experiments where neutrophils from patients with CGD, lacking NADPH oxidase activity, while unable to kill some bacteria can still kill others. In addition, others have found that crude fractions of neutrophils were able to kill gram-negative bacteria (Borregaard and Cowland 1997). Granule constituents play various roles in nonoxidative killing of microorganisms. These mechanisms are continuing to be an area of major research interest. Some of the granule enzyme components show direct antimicrobial activities and in purified forms can kill bacteria. Others, although not directly microbicidal, are involved in the digestion of the bacteria. Nonenzymatic granule proteins have also been shown to be highly antimicrobial. The following azurophilic granule constituents are of interest in relation to nonoxidative killing of microbial pathogens:

- Defensins, cationic peptides of 3.5–4.5 kDa, have a broad-spectrum antimicrobial activity (Lehrer and Ganz 1990). Both α- and β-defensins have been found

Table 2 *An abridged summary of the two major neutrophil granule constituents*[a]

Azurophilic/primary granules	Specific/secondary granules
Myeloperoxidase	Lysozyme
β-Glucuronidase	Lactoferrin
Elastase	Vitamin B_{12}-binding protein
Cathepsin G	Receptors – CR3, fMLP receptor
Defensins	Components of NADPH oxidase
BPI	
Lysozyme	

fMLP, formyl–methionine–leucine–phenylalanine or f-Met-Leu-Phe; BPI, bactericidal permeability-increasing protein.
a) Note that these two granules need to be considered along with a tertiary granule (gelatinase granules) and secretory vesicles.

in these neutrophil granules. The peptides show cytotoxic activity towards fungi, parasites, and gram-negative bacteria. They are released into the phagocytic vacuole during phagocytosis of bacteria.

- Serprocidins such as elastase, azurocidin, and cathepsin G, which have microbicidal activity, are also contained in azurophilic granules (Edwards 1994). This microbicidal activity is independent of proteolytic action.
- Cathepsin G is active against a range of gram-positive and gram-negative bacteria, particularly against *Neisseria gonorrheae* and fungi.
- A highly cationic protein (bactericidal/permeability – increasing protein) with marked bactericidal activity, particularly towards gram-negative bacteria, is also found in azurophilic granules (Elsbach and Weiss 1983). The molecule inserts into bacterial outer membranes causing increased permeability.

Oxidative systems

THE OXYGEN-DEPENDENT RESPIRATORY BURST

When phagocytes adhere to bacteria, one of the most dramatic responses seen is the oxygen-dependent respiratory burst and the generation of a spectrum of reactive oxygen intermediates (ROIs) which are either directly or indirectly microbicidal. The enzyme responsible for this is NADPH oxidase, which consists of several different components that assemble on the phagosome membrane (Heyworth et al. 1999). When neutrophils are stimulated most of the glucose is oxidized via the hexose monophosphate shunt which is closely linked to the reduction of oxygen by the NADPH oxidase. The initial product of the respiratory burst is the production of superoxide (O_2^-).

It was only a few decades ago that the unique characteristics of the neutrophil respiratory burst were first described. It was shown that bacterial killing still occurred in the presence of cyanide, suggesting that mitochondria and the citrate cycle were not involved, consistent with the finding of very few active mitochondria in neutrophils. The ATP generation comes mainly from glycolysis, which does not require oxygen, and this is considered as an advantage because neutrophils need to kill microorganisms in oxygen-depleted tissue sites. Later, it became evident that the majority of the oxygen consumed by the neutrophil was converted to O_2^- (Barbior et al. 1973; Fridovich 1978). Thus, during a respiratory burst, glucose is oxidized via the hexose monophosphate shunt, generating NADPH which together with oxygen provides the source of electrons to produce superoxide anion. From O_2^- several ROIs are formed in the phagocytic vacuole. These are shown below.

$$\underset{\text{(Superoxide)}}{O_2^-} + \underset{}{O_2^-} + 2H + \xrightarrow[\text{Dismutase}]{\text{Superoxide}} \underset{\text{(Hydrogen Peroxide)}}{O_2 + H_2O_2}$$

Haber–Weiss reaction:

$$O_2^- + Fe^{3+} \rightarrow O_2 + Fe^{2+}$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + \underset{\text{(Hydroxyl radical)}}{OH^{\cdot}} + \underset{\text{(Hydroxyl ion)}}{OH^-}$$

The activation of the respiratory burst oxidase can be demonstrated in the reduction of nitroblue tetrazolium (NBT) by the cells which causes the dye to change from a yellow, soluble compound to a blue–black, formazan-insoluble substance in the cell (Figure 5).

COMPONENTS AND ASSEMBLY OF NADPH OXIDASE

NADPH is essentially dormant and becomes rapidly activated after the stimulation of appropriate intracellular signals by agonists ligating the cell surface receptors on neutrophils (Heyworth et al. 1999). Activation occurs once the various components become rapidly assembled at the plasma membrane (vacuole membrane), involving both membrane and cytosolic components of this system (Figure 6). Within the membrane is a unique cytochrome b_{245} (Segal and Jones 1978), a heterodimer of two subunits, $gp91^{phox}$ and $p22^{phox}$, suggested to contain two different types of redox centers. There is one flavin adenine dinucleotide (FAD) domain and at least two heme prosthetic groups (Babior and Kipnes 1977; Segal et al. 1992). The three cytosolic proteins are believed to be necessary to associate with the cytochrome at the membrane, $p40^{phox}$, $p47^{phox}$, and $p67^{phox}$, forming the active enzyme system (Wientjes et al. 1993; Heyworth et al. 1999). Other constituents such as the small GTP-binding proteins are also involved (Heyworth et al. 1999). The oxidase is strategically located to generate ROIs in the vacuole containing the ingested bacteria. Consequently, the binding site for the substrate, NADPH, is on the cytoplasmic side and superoxide is formed at the phagosome membrane side (Figure 6).

MYELOPEROXIDASE–H_2O_2–HALIDE SYSTEM

Myeloperoxidase is present in very high amounts in neutrophil azurophilic granules. During phagocytosis, activation of the respiratory burst is accompanied by degranulation, resulting in release of H_2O_2 and MPO into the phagosome. Interestingly, some of the bacteria phagocytosed can also be a source of H_2O_2. Chloride is then oxidized to hypochlorite (HOCl) by the MPO and H_2O_2. The system produces other toxic agents, including chloramines, hydroxyl radicals, and singlet oxygen.

$$H_2O_2 + 2Cl^- \xrightarrow{MPO} 2HOCl$$

This system causes destruction of microorganisms in phagocytic vacuoles in two main ways: by halogenation and by oxidation (Klebanoff 1968, 1999); it has been

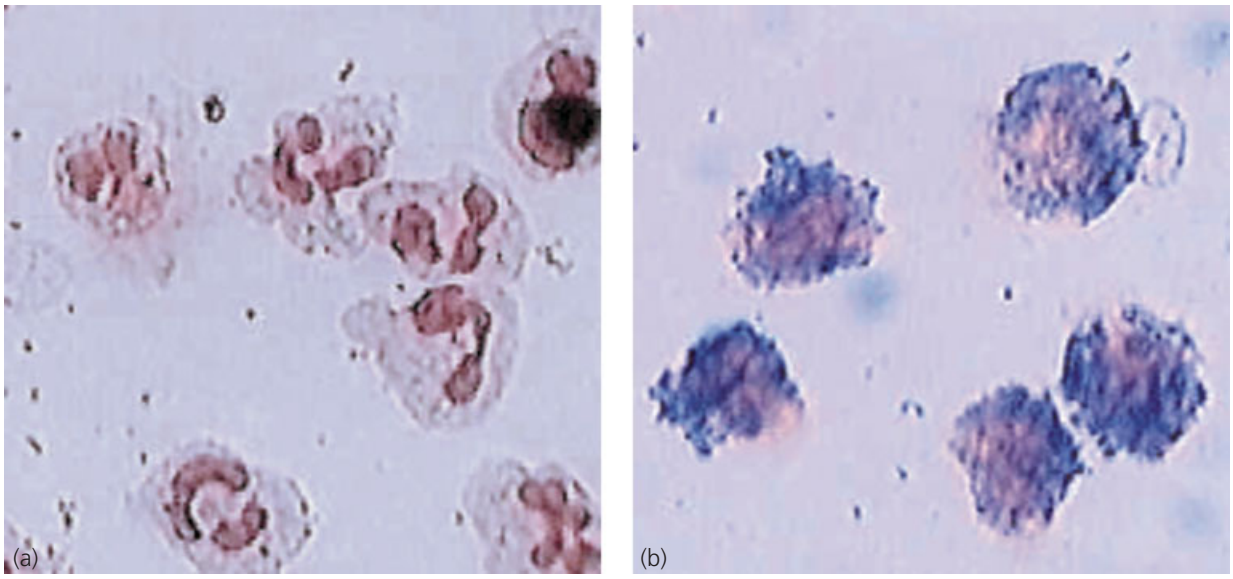

Figure 5 *Oxidative burst activity in stimulated neutrophils shown by the nitroblue tetrazolium (NBT) reduction assay.* **(a)** *Non-stimulated neutrophils lacking positive NBT staining compared with phorbol myristate acetate (PMA)-activated neutrophils* **(b)**, *which show the blue–black formazan deposits.*

shown to damage/kill a wide range of microorganisms, including bacteria, protozoan parasites and metazoan parasites (Klebanoff 1999), as well as tumor tissues during inflammation (Klebanoff 1999). Bacterial toxins are also inactivated by the MPO–H_2O_2–halide system.

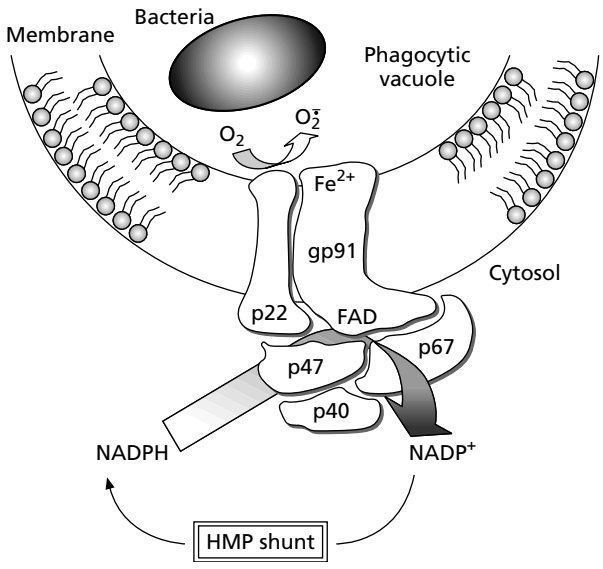

Figure 6 *The positioning of the activated oxidase in the membrane of the phagocytic vacuole and the link between the oxidation of NADPH and the generation and release of superoxide into the bacteria-containing phagocytic vacuole. The components of the NADPH oxidase are also depicted. The cytochrome* b *$gp91^{phox}$ and $p22^{phox}$ are localized in the membrane and require the recruitment of at least three cytosolic components, $p40^{phox}$, $p47^{phox}$, and $p67^{phox}$ for the complex to act as the oxidase. The substrate for oxidase is generated when glucose is oxidized via the hexose monophosphate (HMP) shunt. In this reaction two electrons are transferred from the NADPH to FAD, followed by the reduction of Fe^{3+} to Fe^{2+} and direct binding of the reduced hemes to oxygen molecules to form superoxide.*

INTRACELLULAR SIGNALING AND NEUTROPHIL FUNCTIONS

The chemoattractant coupling of the surface receptor is coupled to the intracellular second messengers by the heterotrimeric G-proteins (guanine nucleotide-binding proteins). The second messengers, inositol triphosphate (IP_3), Ca^{2+} mobilization, phosphatidic acid (PA), arachidonic acid (AA), and cyclic nucleotides, have all been shown to participate in cell movement. Antibody- and/or complement-opsonized microorganisms ligate the FcγR and CR3 receptors and induce signal transduction mechanisms, involving G-proteins, protein kinases, and phospholipids, which control phagocytosis, activation of NADPH oxidase, and degranulation.

Nonstimulated neutrophils express a transmembrane FcγRIIA and FcγRIIIB, which is the GDP-dissociation inhibitory factor GPI linked to the membrane. Ligation and crosslinking of these receptors stimulates tyrosine phosphorylation as well as phospholipase Cγ. This then leads to the activation of protein kinase C (PKC), Ca^{2+} mobilization, and activation of phosphotidylinositol-3-kinase (PI3-K) signaling pathways. These molecules are then responsible for activating downstream signals such as the mitogen-activated protein (MAP) kinases, leading to a network interaction to stimulate functional responses including phagocytosis, activation of the respiratory burst, and degranulation. The complement receptors such as CR1 and CR2 are likely to associate with the Fcγ receptors to promote these responses.

Ligation of the CR3 (CD18/CD11b) on neutrophils leads to the activation of upstream signals including PI3-K. A number of intracellular molecules have been shown to regulate the various neutrophil functions. The PI3-K, a family of kinases, phosphorylates inositol-containing phospholipids to form phosphatidyl inositol. Two classes of PI3-K have been identified in neutrophils: the classic class Ia (p85/p110) heterodimer and a G-protein βγ subunit-regulated PI3-K. PI3-K is required for stimulating the respiratory burst and degranulation.

Protein kinase C is a family of serine/threonine kinases that resides in the cytoplasm and translocates to the particulate fraction (plasma membrane and cytoskeleton associated) after neutrophil stimulation. Translocation of PKC is closely associated with its activation. Approximately 12 different PKC isozymes have been described and these will vary from cell type to cell type. They are also activated differently by individual agonists and various isozymes may be responsible for different cellular functions. In neutrophils the expression of PKCα, β1, β11, δ, and ξ has been reported. Evidence has been presented that PKC is required for the neutrophil functions of chemotaxis, respiratory burst, and phagocytosis.

There are three distinct families of MAP kinases recognized: the extracellular signal-regulated kinase (ERK), c-Jun NH_2-terminal kinase (JNK), and p38. The role of JNK in neutrophil function has not been identified because various agonists fail to activate JNK, unless special conditions are met such as pre-adherence of cells and addition of protease inhibitors (Avdi et al. 2001).

ERK1 and ERK2, which can be activated via various receptors including FcγR, have been shown to play a role in the activation of the oxidase by phosphorylating $p47^{phox}$, a cytosolic component of the oxidase. More recent studies have, however, demonstrated that the ERK cascade plays a major role in chemokinesis and a lesser role in bacterial and fungal killing by neutrophils (Hii et al. 1999).

Of the four recognized isoforms of p38, neutrophils express the α and δ isoforms. Activation of p38 can be achieved by both G-protein-coupled receptors as well as non-G-protein-coupled receptors. In terms of neutrophil functions, p38 plays a role in chemotaxis, respiratory burst, degranulation, and apoptosis.

NEUTROPHIL PRIMING

There is now overwhelming evidence that neutrophils can be educated for increased performance in their antimicrobial activity (Coffey 1992). A variety of exogenous and endogenous mediators has been shown to prime neutrophils for increased antimicrobial function but perhaps the most interesting have been the cytokines (Ferrante 1992). Priming of neutrophils requires short-term exposure to cytokines and in most cases is optimal with a 30-min pre-treatment time (Ferrante et al. 1993b). Cytokine-primed neutrophils are then able to respond more effectively to a challenging agonist, be it soluble or particulate, including microbial pathogens. This has been shown as an increased expression of functional surface receptors (CR3, FcγR), increased particle adhesion and phagocytosis, increased release of ROIs and degranulation, and increase in microbial killing or tissue damage (Klebanoff et al. 1986; Ferrante et al. 1987; Ferrante 1989).

Many cytokines have been shown to alter neutrophil responses, in terms of priming. These include TNF-α, TNF-β, GM-CSF, G-CSF, IL-1, IFN-γ, IFN-β, IL-2, and IL-8 (Coffey 1992). Receptors for many of these cytokines have been described on neutrophils. Treatment of neutrophils with some of these cytokines alone produces little response, fulfilling the role as primers and enabling the cell to undergo rapid stimulation upon engagement of microbial pathogens (Ferrante 1992). Increases in formyl-methionine-leucine-phenylalanine (fMLP) receptor, CR3, and FcγR expression have been described during the priming phase (Klebanoff et al. 1986; Kumaratilake et al. 1995). Priming of neutrophils can also be achieved by exposing the cells to cytokine-rich supernatants from stimulated T cells or macrophages, or from purified cytokine from these cells (Kumaratilake et al. 1991; Ferrante 1992) and even after direct contact with activated T lymphocytes (Zhang et al. 1992). Peripheral blood mononuclear cells stimulated with heat-killed *Staphylococcus aureus* produce high amounts of TNF-α and IL-1. These supernatants were found to prime neutrophils for increased killing of opsonized *S. aureus* and this property was primarily caused by TNF-α (Ferrante 1992). Table 3 outlines the properties of TNF-α more extensively.

An examination of the various models of microbial killing by cytokine-primed neutrophils shows that, in models such as the killing of opsonized, pathogenic, free-living amoebae, e.g. *Naegeria fowleri*, unprimed neutrophils have little effect and only attain amoebicidal properties once primed with cytokines (Ferrante and Mocatta 1984). In other cases, the neutrophils kill the bacteria, such as *S. aureus*, but this killing can be markedly improved by priming the neutrophils (Ferrante et al. 1993b). Interestingly, Kowanko et al. (1996) showed that such priming for killing of *S. aureus* was oxygen-dependent, but oxygen-independent for killing of intraerythrocytic asexual blood stages of *Plasmodium falciparum*. In the case of blood stages of *P. falciparum*, the merozoite and asexual intraerythrocytic stages, TNF-primed neutrophils will also show enhanced killing in the absence of opsonins, although it is much more marked when the parasites have been opsonized with antibody and complement (Kumaratilake et al. 1991, 1992; Ferrante et al. 1993a). This suggests that priming may also enhance killing when recognition is via a pattern-recognition system.

Table 3 *Properties of TNF-primed neutrophils*

Increased expression of CR3, FcγR, fMLPR
Inhibited migration
Increased agonist-induced respiratory burst in response to:
fMLP
opsonized bacteria
opsonized yeast/fungi
opsonized parasites
Increased agonist-induced degranulation in response to:
fMLP
opsonized bacteria
opsonized yeast/fungi
opsonized parasites
Increased microbial killing, e.g. for
Staphylococcus aureus
Streptococcus pneumoniae
Candida albicans
Plasmodium falciparum merozoites and intraerythrocytic asexual blood stage
pathogenic free-living amoebae
Increased tissue damage:
articular cartilage

fMLP, formyl–methionine–lysine–phenylalanine or f-Met-Lys-Phe; fMLPR, fMLP receptor; TNF, tumor necrosis factor.

Neutrophil priming by other exogenous and endogenous inflammatory mediators, apart from cytokines, also occurs, e.g. fMLP, a microbial peptide, is a poor neutrophil stimulator of respiratory burst and degranulation but a strong chemotactic agent and a strong neutrophil priming agent for the former two responses. This thus enables cells to arrive at inflammatory sites relatively controlled and primed to respond to bacteria. Products of the cyclooxygenase pathway, in particular LTB_4 and 5-oxo-6,8,11,14-eicosatetraenoic acid (5-oxo-ETE), will also act as neutrophil priming agents to increase neutrophil adhesion, superoxide production, and degranulation (Powell et al. 1997; Ferrante et al. 1999).

ROLE OF NEUTROPHILS IN MICROBIAL DEFENSE

The importance of neutrophils in immunity to bacterial and fungal infections has been appreciated for over a century and their role in immunity to protozoan and metazoan parasites has been more recently recognized. The first line of evidence for a role of neutrophils in resistance against infection is demonstrated by the susceptibility of microbial pathogens to various products of neutrophils. Second, provided that the relevant opsonic factors are present, neutrophils have been shown to engulf bacteria such as *S. aureus*, *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, and *Haemophilus influenzae* and also fungi such as *Candida albicans*. Asexual intraerythrocytic blood stages of *P. falciparum* are readily engulfed and destroyed by neutrophils (Ferrante et al. 1993a). Larger unicellular (amoebae) and multicellular (such as nematodes, microfilaria, etc.) parasites are, however, killed by an extracellular mechanism.

There is an overwhelming demonstration of the accumulation of neutrophils at sites of microbial pathogens in the tissues. These include numerous types of bacteria, fungi, and parasites. It is not uncommon to find neutrophils with engulfed bacteria at these sites. Furthermore, a range of microbial products promotes neutrophil accumulation at inflammatory sites.

Experiments of nature demonstrate an important role of neutrophils in resistance against infection. Neutropenia, whether hereditary or drug induced, leads to increased risk of infection and death from overwhelming infection. Neutropenic patients are in particular susceptible to both bacterial and fungal infections. Several neutrophil functional defects also predispose children to severe/recurrent life-threatening infection.

In experimental animal models of infection, the role of the neutrophil has also been established. Experimentally induced neutropenia makes animals highly susceptible to bacterial, fungal, and parasitic infections. In some cases, such as infections with nematodes and pathogenic free-living amoebae, depletion of neutrophils from immune mice renders them highly susceptible to these infections (Penttila et al. 1985; Ferrante 1992).

Primed neutrophils show increase antimicrobial activity. In vitro there is evidence that neutrophil-mediated killing of microbial pathogens can be increased dramatically by priming with cytokines such as TNF, GM-CSF, IL-1, LTs, and IFN-γ (Coffey 1992; Tan et al. 1995). In some cases neutrophils fail to show any significant killing of the microorganism unless the cells have been primed with these agents (Ferrante 1992). It is interesting that human peripheral blood mononuclear cells stimulated with heat-killed *S. aureus* generate supernatants that are very effective neutrophil-priming agents, and this activity can be ablated by treatment with anti-TNF antibodies (Ferrante 1992). The role of TNF-primed neutrophils in microbial killing has been extended to several bacteria, including *H. influenzae* and *Legionella pneumophila* (Blanchard 1992; Tan et al. 1995).

Interestingly, neutrophils recovered from immune mice can kill microbial pathogens at significantly greater rates (Ferrante 1992; Penttila et al. 1984). In other studies with experimental infection models, it has been shown that infusion of cytokines increases the resistance against bacterial, fungal, and parasitic infection. Furthermore, immunized mice resistant to microbial pathogens can be severely compromised by treatment with anti-TNF or anti-GM-CSF antibodies (Coffey 1992; Ferrante 1992).

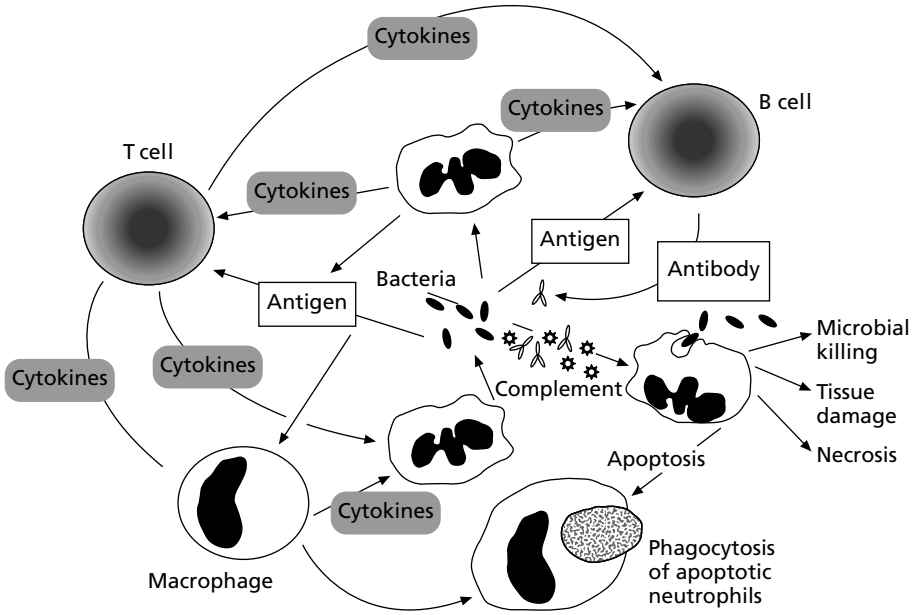

Figure 7 *An abridged version of the intricate interrelationship of neutrophils, lymphocytes, and mononuclear phagocytes. The main function of the neutrophil is to phagocytose microbial pathogens. Phagocytosis is promoted by coating of the bacteria with antibody and complement. Neutrophil recognition of particles, phagocytosis, and killing is greatly accelerated by priming neutrophils with cytokines released by T lymphocytes and macrophages. Downregulation of tissue damage by activated neutrophils is achieved through the stimulation of apoptosis in neutrophils and engulfment by macrophages. The likely contribution of neutrophils to T- and B-lymphocyte responses is also demonstrated in this scheme.*

APOPTOSIS

Activation of a cell-intrinsic suicide program results in programmed cell death or apoptosis, which can be distinguished from degenerative cell death or necrosis. The dying cell is characterized by several properties such as shrinkage, crenation, condensed chromatin, and DNA fragmentation. Apoptosis is controlled by many types of endogenous and exogenous mediators. Neutrophil apoptosis is considered a host tissue-protective property because these cells lose their functional receptors and ability to produce toxic products, and are eventually engulfed and removed by macrophages (Fanning et al. 1999). This aging fate of neutrophils was first indicated by Metchnikoff (1893).

Neutrophils reaching inflammatory sites engulf and kill microbial pathogens and die at these sites. Death via necrosis leads to the release of tissue-damaging products. Thus, the physiological response, besides initiating events that lead to microbial killing, also ensures the subsequent initiation of apoptotic signals to downregulate the powerful oxidative and nonoxidative responses of the neutrophils and finally leads to the clearance of neutrophils from these sites (Newman et al. 1982). Inflammatory leukocytes, such as activated neutrophils, express Fas, a death factor receptor. Ligation of this receptor transduces the intracellular signals for apoptotic death (French and Tschopp 1997). Apoptotic signals in neutrophils lead to a loss in their ability to respond to inflammatory mediators because their cell surface receptors are downregulated. There is also a major loss in chemotactic, phagocytic, degranulation, and respiratory burst function. Further isolation from their toxic products results from the engulfment of the apoptotic neutrophils by macrophages. Essentially, this is a means of limiting tissue injury as demonstrated in Figure 7. It is believed that apoptotic neutrophils are recognized by either the exposure of phosphatidylserine on their surface and/or expression of a thrombospondin-binding moiety that recognizes thrombospondin and allows binding to the vitronectin (CD16) receptor on macrophages (Fadok et al. 1992).

Inflammatory fluids contain many different factors some of which protect against apoptosis. The cytokines G-CSF, GM-CSF and IL-2, as well as LPS and glucocorticoids, inhibit neutrophil apoptosis. However, conflicting data have been presented for TNF and fMLP.

PRODUCTION OF INFLAMMATORY MEDIATORS

Neutrophils play a central role in the inflammatory response in contributing to the inflammatory mediator network by releasing a range of mediators, including oxygen radicals, enzymes such as MPO, LTs, and prostaglandins (PGs) as well as a range of cytokines (Table 4). In this manner, neutrophils could have a significant influence on the acute and chronic inflammatory responses, as well as the immune response, by regulating T lymphocyte, macrophage, and antigen-presenting cell functions (Figure 8).

Table 4 *Products of stimulated neutrophils which may regulate inflammation and immune responses*

Class of mediator	Mediator
Lipids	PAF, AA, LTB4, PGE2, lipoxins, TXA4, 5-oxo-ETE
Cytokines	IL-1, TNF-α, IFN-α, IL-8, IL-6, TGF-β, IL-12, IL-10, IL-3, G-CSF, M-CSF, MCP-1, MIP-2, IL-1α

AA, arachidonic acid; CSF, colony-stimulating factor; G-CSF, granulocyte CSF; M-CSF, macrophage CSF; IFN, interferon; IL, interleukin; LT, leukotriene; MCP, monocytic chemotactic peptide; MIP, macrophage inflammatory protein; PAF, platelet-activating factor; PG, prostaglandin; 5-oxo-ETE, 5-oxo-6,8,11,14-eicosatetraenoic acid; TGF, transforming growth factor; TNF, tumor necrosis factor; Tx, thromboxane.

Lipid inflammatory mediators

Through the action of a number of cellular enzymes, such as phospholipase (PLA_2), cyclooxygenases, and lipoxygenases, neutrophils release a range of mediators (see Table 4). Several mediators produced are known for their marked effects on inflammation and immune responses (Haeggstrom and Serhan 1999). These include arachidonic acid (AA), LTB_4, PGE_2, and platelet-activating factor (PAF), all of which regulate neutrophil, eosinophil, basophil, T-lymphocyte, macrophage, and endothelial cell function.

Platelet-activating factor plays a role in both acute and chronic inflammation. It stimulates a range of neutrophil activities including chemotaxis, aggregation, adherence, respiratory burst, and degranulation. LTs have diverse effects and may promote the pathophysiological process during infection by stimulating endothelial cell function, upregulating macrophage, and lymphocyte functions. This contrasts with their role in promoting pathophysiology in rheumatoid arthritis, airway diseases such as asthma and adult respiratory distress syndrome, allergic inflammation, and cystic fibrosis (Penrose et al. 1999).

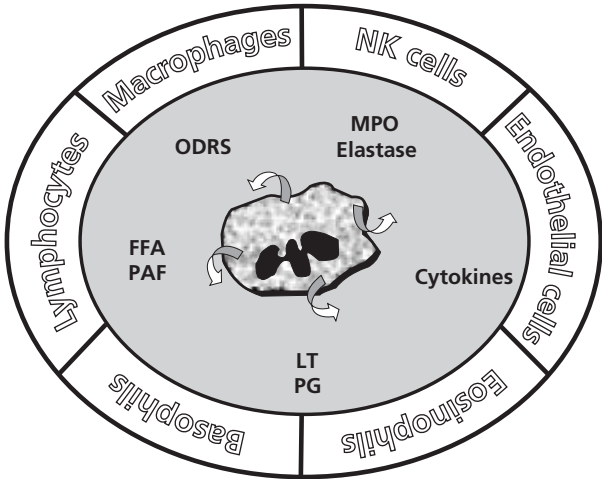

Figure 8 *Diagrammatic summary of mediators released by stimulated neutrophils and the cells that these may regulate. FFA, free fatty acid; LT, leukotriene; MPO, myeloperoxidase; NK, natural killer; PAF, platelet-activating factor; PG, prostaglandin.*

Prostaglandins, produced during the oxidation of AA via the cyclooxygenase pathway, have a wide range of effects and play a role in both physiological and pathophysiological responses (Griffith 1999). These regulate pain, edema, fever, and granulocyte, macrophage and lymphocyte function. PGE_2 suppresses neutrophil functions, chemotaxis, and respiratory burst. It also inhibits the activation of mononuclear phagocytes, depressing TNF synthesis. Inhibition of T-cell function, lymphoproliferation, and cytokine production are also inhibited by PGE_2, in particular the Th1 cytokines.

Cytokines

Although mature neutrophils have been considered as end cells not capable of RNA and protein synthesis, more recent evidence suggests that they can be induced to synthesize new proteins (Cassatella 1999). Most interesting has been the discovery that neutrophils can produce a wide range of cytokines (see Table 4). In this manner, the cells can regulate immune reactions. Although these cytokines are produced in very low amounts by neutrophils compared with macrophages, with a predominance of neutrophils in some inflammatory sites, it is possible that neutrophils release effective amounts of these cytokines to control other cells of the inflammatory response. Through the ability to release the spectrum of cytokines outlined in Table 4, neutrophils have the potential to control migration of mononuclear cells into tissues as well as to promote their activation. Thus, T lymphocytes as well as B lymphocytes may be under neutrophil control through the release of cytokines such as IL-1, IL-6, IL-10, IL-3, etc. Similarly, these and others will influence the function of mononuclear phagocytes and APCs. In this manner neutrophils that arrive early in inflammatory sites and antigen injection sites are likely to have some influence on the inflammatory response. The examination of the spectrum of cytokines produced by neutrophils shows that these may be of either Th1 or Th2 type, suggesting that the neutrophil could influence the type of immune response elicited by microbial antigens. Similarly, there are cytokines that regulate macrophage functions.

Interestingly, apart from a wide range of compounds able to stimulate cytokine production by neutrophils, there is also evidence that different stimulators may

cause the production of different types of cytokines and that both extrinsic and intrinsic stimulators can induce cytokine production in these cells (Cassatella 1999). Extrinsic agents include bacteria, fungi, and viruses and fMLP. Intrinsic stimulators include LTB_4, PAF, C5a and of course the cytokines themselves. The ability to produce IL-1 receptor antagonist (IL-1ra) enables the neutrophil to regulate the activity of the pyrogenic cytokine, IL-1.

Neutrophils, through the release of IL-8 (a CXC chemokine), can regulate the migration of other neutrophils and stimulate these cells for antimicrobial functions. As IL-8 is also chemotactic for T lymphocytes and basophils, neutrophils could be involved in exerting influence on these cell types during inflammation. Other CXC chemokines produced by neutrophils that have effects similar to IL-8 on neutrophils are growth-related gene product α/β (GROα/β) and IFN-γ-inducible protein (IP-10) which are mainly chemotactic for natural killer (NK) cells, and may therefore be important in the recruitment of these cells, as well as T cells and monocytes. Neutrophils can also secrete CC chemokines, such as macrophage inflammatory protein 1-α/β (MIP-α/β), which have potent chemotactic properties for monocytes and T lymphocytes.

The three cytokines that are classically referred to as the pyrogenic cytokines, TNF-α, IL-1, and IL-6, can also be produced by neutrophils. Thus, there is the potential for neutrophils to mediate pathogenesis by releasing these cytokines. Both TNF-α and IL-1 are also known to prime neutrophils for increased antimicrobial activity and it is possible that neutrophils may autoregulate their antimicrobial functions in this manner. The ability of these cytokines to regulate lymphocyte activation and differentiation enables neutrophils also to influence this property of the immunological system. The expression of the CD30 ligand (CD30L), a member of the nerve growth factor (NGF)/TNF receptor super family) on neutrophils suggests that neutrophils could interact via CD30 on T lymphocytes to promote activation of these cells. Neutrophils can also produce IL-1ra, which controls the effects of IL-1. This represents another level of regulation of inflammation and pathogenesis by neutrophils. A variety of agents is also capable of inducing the production of IL-1ra in neutrophils. The influence that stimulated the effects that neutrophils may have on the development of the Th1 versus the Th2 response can be extrapolated from their reported ability to produce and release IL-12, which induces IFN-γ production from NK cells and T lymphocytes, and a cytokine that facilitates Th1 lymphocyte responses and thereby suppresses IgE formation.

Although the amount of cytokine produced by neutrophils compared with macrophages is very small, in a number of inflammatory conditions neutrophils are present in substantial numbers and may contribute to immunoregulation through the release of selective cytokine patterns. Important consideration needs, however, to be given in specific situations, e.g. the ability of neutrophils to produce IFN-α in similar levels to that produced by monocytes when infected with Sendai virus suggests an important role for neutrophils in defense against viruses.

NEUTROPHIL IMMUNODEFICIENCY DISEASES

Congenital defects

The spectrum of primary neutrophil disorders is listed in Table 5. These range from disorders in which the numbers of neutrophils are too low to cope with infections to others that show functional defects of chemotaxis, adhesion, respiratory burst, and degranulation (Quile et al. 1996).

NEUTROPENIA

Leukocyte counts of below 1500 cells/mm^2 will increase the risk of infection in a progressive manner as the numbers continue to decrease below this level. A dramatic increase in incidence of infection is seen once the levels are below 500 cells/mm^2. Hereditary neutropenia occurs, ranging from severe, as seen in infantile genetic agranulocytosis, to moderate, as in familial neutropenia. The former disorder is a result of maturation arrest that is inherited in an autosomal recessive manner. Patients with hereditary neutropenia experience severe infection and death in infancy. Another neutropenia characterized by the periodic disappearance of neutrophils from the blood is cyclic neutropenia, an autosomal dominant disorder. During the period of low neutrophil counts, the patient can present with cutaneous infections and associated fever and malaise. Overcoming the neutropenic oscillations can be achieved with G-CSF or prednisolone treatment.

LEUKOCYTE ADHESION DEFICIENCY

Two types of leukocyte adhesion deficiency (LAD) have been described. In type 1 there is a defect in the integrin molecule. This is the result of an abnormal β-chain synthesis presenting as a spectrum of mutations in the β gene. Although the α chain is produced in normal amounts, the assembly of the α and β chains is poor and is poorly transported to the cell surface. The neutrophils have impaired adherence, chemotaxis, and respiratory burst in response to complement- but not antibody-coated particles. Although cells from these individuals display normal rolling adhesion, they cannot bind firmly to venule walls and hence are unable to migrate out of the blood vessels. This is an autosomal recessive disease after a history of consanguinity. Patients are likely to present with prolonged, as well as recurrent, infections with *Pseudomonas* and *Staphylococcus* spp. during

Table 5 *Summary of primary immunodeficiencies of neutrophils*

Disease	Function affected
Neutropenia	
Infantile genetic agranulocytosis	
Familial neutropenia	
Cyclic neutropenia	
Leukocyte adhesion deficiency	
Type 1 (CR3 deficiency)	Adhesion, chemotaxis, aggregation, spreading
Type 2 (sialyl Lewis deficiency)	Selectin ligation, rolling, adhesion
Chronic granulomatosis disease	
Membrane defects of	Oxidase (lack of production of oxygen reactive species)
$gp91^{phox}$	
$p22^{phox}$	
Cytosol defects of	
$p47^{phox}$	
$p67^{phox}$	
Chédiak–Higashi syndrome	Granules (giant lysosomal granules): decreased chemotaxis, degranulation and bactericidal activity, increased H_2O_2 production, deficient elastase and cathepsin G
Specific granule deficiency	Specific granules are absent; decreased chemotaxis, O_2^- production, bactericidal activity
Myeloperoxidase (MPO) deficiency	Absent or low MPO
Hyper-IgE (Job's) syndrome	Chemotactic defect

infancy. Poor wound healing can also occur which can manifest in delayed umbilical cord separation. Infection sites include the intestinal tract, soft tissues, and mucosal surfaces. Those individuals who survive infancy are likely to develop acute gingivitis and eventually gingival hypertrophy. Patients with the moderate phenotype may survive to adulthood. It has been estimated that two-fifths of patients with type 1 LAD die before 2 years of age.

In LAD type 2, the defect is an absence of expression of the primary selectin ligand sLe^x on the neutrophils. This is an autosomal recessive disorder in which poor random mobility and chemotactic responses by neutrophils are exhibited. However, the respiratory burst response to opsonized particles does lie within a normal range. The neutrophils fail to adhere to stimulated venules and lack rolling adhesion. As the integrin expression is normal the neutrophils still adhere to blood vessel walls. Patients present from early childhood with recurrent bacterial infections.

CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease is a group of disorders of phagocyte oxidative respiratory burst which can be inherited either in an X-linked or an autosomal recessive manner. The basis of this deficiency is the result of a defect in one of several components that make up the oxidase. Abnormalities in the membrane-bound component $gp91^{phox}$ of cytochrome b_{558} give rise to the most common form of CGD (55–60 percent). Defects of the light chain of the membrane cytochrome, $gp22^{phox}$ have also been described with an approximate frequency of 5 percent. Defects in the cytosolic components $p47^{phox}$ and $p67^{phox}$ account for 30–35 and 5 percent of the CGD, respectively.

Chronic granulomatous disease is manifested clinically by the development of serious infections in early childhood. Pneumonia, skin and soft tissue infections, lung abscesses, osteomyelitis, and hepatic abscesses may be common. The majority of the infections can be accounted for by *S. aureus* and *Serratia burkholderia* and, less commonly, by infection with *Aspergillus* and *Nocardia* spp. Management of patients with CGD primarily involves aggressive antibiotic cover, surgical drainage, and even white cell transfusion. Prophylactic IFN-γ has recently been employed which has reduced the occurrence of these life-threatening infections. It is recommended that IFN-γ be used in conjunction with trimethoprim–sulfamethoxazole. Efforts are being made at present to use gene therapy to correct the defect in CGD, with some early success with retroviral-mediated gene therapy for $p47^{phox}$ deficiency.

CHÉDIAK–HIGASHI SYNDROME

Neutrophils from patients with Chédiak–Higashi syndrome (CHS) show abnormal (large) granules as a result of fusion of two granules. Although the cells can phagocytose particles, chemotaxis and microbial killing

are abnormal. The respiratory burst and its ability to produce oxygen-reactive species is normal but the release of MPO is delayed. The neutrophils show deficiency in cathepsin G and elastase. There is abnormal fusion of granules, possibly as a result of defects in membrane fluidity and the microtubules. The bactericidal activity of the cell is greatly diminished as a consequence of a delay in the delivery of granule constituents to the phagocytic vacuole. Apart from neutrophils, defective functions of other cells of the immune system occur, impaired NK cell activity, and antibody-dependent, cell-mediated cytotoxicity. Cytotoxic T-cell activity is also affected. Decreased neutrophil and monocyte migration and reduced bactericidal activity are likely to explain the delayed inflammatory response and the increased susceptibility to infections expressed by patients with CHS, who usually die from infections at an early age.

SPECIFIC GRANULE DEFICIENCY

Patients with an absence of specific granules have been described. Their neutrophils lack specific granule constituents such as lactoferrin and vitamin B_{12}-binding protein. However, it has also been found that the cells are devoid of defensins, which are major components of the azurophilic granule. Thus, there is likely to be a more general defect. As a result of the lack of specific granules, upregulation of functional surface receptors is compromised. It is not surprising to find that neutrophils have chemotactic defects. Patients present with recurrent infections.

MYELOPEROXIDASE DEFICIENCY

This is the most common of the neutrophil disorders. This deficiency may go unnoticed because, in many individuals, the susceptibility to infection is not easily recognized and only a few cases have been reported with serious infections, mainly candidiasis. Killing of microorganisms is delayed because of the absence of MPO. Other functions such as chemotaxis, phagocytosis, respiratory burst, and degranulation are normal. Superoxide levels may be increased because of the lack of MPO and this may compensate for the lack of killing of bacteria via the MPO–H_2O_2–halide system.

HYPER-IgE SYNDROME (JOB'S SYNDROME)

Patients with extremely high levels of IgE have depressed neutrophil chemotaxis and depressed acute inflammation. One of the suggested causes of this is the release of histamine. These patients present with recurrent cutaneous and sinopulmonary infections. Characteristically, the infections are caused by *S. aureus*, but in some cases *H. influenzae* causes pulmonary infections. T lymphocytes from these patients have also been reported to be deficient in IFN-γ production and it has been suggested that an imbalance between IL-4 and IFN-γ production leads to downstream switching of immunoglobulin genes, giving rise to elevated IgE. Although some sporadic cases have been described, hyper-IgE syndrome is an autosomal dominant disease.

Acquired immunodeficiencies of neutrophils

Secondary immunodeficiency of neutrophils, as with primary immunodeficiency, spans a wide range, but will usually occur in combinations because of the nonspecific nature of the causative agent. This includes malnutrition, cancer and chemotherapy, infection, immaturity of the immune system in neonates, and deterioration as a result of age. The hallmark of these diseases is the increased severity and recurrence of infection, as for primary immunodeficiencies, although it is considered not to be as severe.

Drug therapy is responsible for acquired neutropenias, seen in patients undergoing chemotherapy for immunological and neoplastic disorders. Idiosyncratic reaction may occur when drugs such as penicillin, cephalosporins, vancomycin, sulfonamides, and phenothiazines are used. With antibody-mediated neutrophil damage or hypersplenism, neutropenia is experienced because of sequestration of the neutrophils in splenic tissue (Palmblad et al. 2001).

Diseases in which circulating immune complexes occur, including rheumatoid arthritis, systemic lupus erythematosus, etc., can show a high rate of oxidative respiratory burst and granule release, and decrease in chemotactic responses. Other forms of serum chemotactic inhibitors have been found. Bactericidal products may cause neutrophil chemotactic abnormalities as seen, for example, in some patients with gingival infections with *Bacterioides ochraceus* (Clark et al. 1977).

Treatment of these infections restores chemotactic responsiveness. IgG antineutrophil antibodies have also been implicated with neutrophil chemotactic responsiveness seen in patients with recurrent skin infections. Other agents that can cause decreased chemotactic responsiveness include the drugs amphotericin B and tetracyclines, and alcohol. Other causes of acquired chemotactic immunodeficiencies include malnutrition, physiological immaturity of the neonate, viral infections, sepsis, and thermal injury. In leukemia, thermal injury, various autoimmune conditions, sepsis, and viral infections, the neutrophil microbicidal activity can also be significantly reduced. Viral infections can lead to decreased neutrophil functions and associated risk of bacterial infections (Faden and Ogra 1986). Thus, during epidemics of influenza, deaths have been associated with bacterial pneumonia. Viruses have been shown to depress neutrophil chemotaxis, phagocytosis, and respiratory burst/intracellular killing.

A range of bacteria as well as fungi and parasites cause depressed neutrophil chemotaxis, phagocytosis, and oxidative burst. The pneumococcal toxin, pneumolysin was found to cause marked inhibition of neutrophil-mediated killing of *S. pneumonia* and the respiratory burst of the cell (Paton and Ferrante 1983).

Therapies for neutrophil disorders

Marked neutropenia and severe neutrophil function defects lead to life-threatening infections (Walsh et al. 1994). Antibiotic prophylaxis is used in most cases, although the development of antibiotic-resistant organisms presents another problem. Other forms of therapies include neutrophil transfusion, bone marrow transplantation, and cytokine infusions.

Neutrophil transfusion is of possible benefit to neutropenic patients with infections, although the results from some of the clinical trials have questioned whether the patients actually benefit. Nevertheless, benefits can be achieved if a careful approach is taken (Strauss 1999). There are various explanations for the inconsistencies in results with this type of therapy, including the severity of the infection and the various antibiotics used. Thus transfusions should be used in combination with the various therapies, antibiotics, immunoglobulin, and recombinant growth factors. The decision to proceed with neutrophil infusion should be guided by ensuring that relevant preparation methods are used and effective doses are given to patients. Neutrophils prepared from donors who have received G-CSF seem to give a more favorable response.

Bone marrow transplantation has been used successfully in LAD and CGD and more recently hemopoietic progenitor cell transfusions have become an attractive option. The treatment of patients with recombinant hemopoietic growth factors such as G-CSF is very attractive; it has proved useful to enhance bone marrow recovery as a consequence of chemotherapy and was beneficial in protecting against infection in these patients. According to reported information, low-dose G-CSF in patients with cyclic and idiopathic neutropenia is effective in elevating circulating neutrophil numbers and decreasing the episodes of fever and infections. In congenital neutropenia high doses of G-CSF are needed.

Trials have also been conducted on the use of G-CSF in non-neutropenic patients with pneumonia. These patients experienced an increase in neutrophil levels as well as clinical improvement. In addition, cytokine therapy has been used in CGD. The incidence of life-threatening infection in CGD patients can be markedly reduced with prophylactic IFN-γ. Both the number and the severity of infections are dramatically reduced (Quie et al. 1996). The action is most likely through a multiple effect, including restoration of some functional oxidase activity, macrophage granule stimulation, and increased expression of functional receptors such as FcγR. This cytokine is recommended in conjunction with antimicrobial agents as a prophylactic for CGD.

Laboratory diagnosis of neutrophil deficiencies

The various neutrophil immunodeficiency syndromes can be easily diagnosed by a series of laboratory tests (Metcalf, Gallin et al. 1986; Kuijpers et al. 1999; Virella 1999). These tests can range from very simple procedures to those requiring much more sophistication. Although some tests will measure a specific pathway, others measure the activity of several pathways culminating in a final event. When the defect in neutrophil function is severe, patients will usually present with recurrent and life-threatening infections. An outline of the tests used to assess the competence of neutrophils in a patient is summarized in Table 6. Usually evaluations would proceed to this group of tests when recurrent bacterial and fungal infections in patients cannot be explained by neutropenia, defects of antibody or complement, and T-cell abnormalities.

Leukocyte adhesion deficiency can be diagnosed by functional and flow cytometric analysis and the two forms, LAD1 and LAD2, should be differentiated. In LAD1 there is deficient expression of the α and β chains

Table 6 *Neutrophil functional tests for diagnosis of primary immunodeficiency*

Function	Tests
LAD1	Adhesion of neutrophils
	Flow cytometry
LAD2	Flow cytometry
Chemotaxis	Migration under agarose
	Boyden chamber
	Modified/commercial Boyden chamber
Phagocytosis	Uptake of yeast particles/by microscopy
	Uptake of particles by flow cytometry
	Radiometric assay
	Erythrocyte lysis assay
NADPH oxidase	NBT assay
	Chemiluminescence (lucigenin)
	$O_2^{\cdot-}$ or H_2O_2 assays
	HMP shunt
MPO	Quantitative leukocyte iodination assay
	MPO enzyme assay
	Histochemical assay
Microbicidal activity	Bactericidal assay
	Fungicidal assay

HMP, hexose monophosphate; LAD, leukocyte adhesion deficiency; MPO, myeloperoxidase; NADPH, reduced nicotinamide adenine dinucleotide phosphate; NBT, nitroblue tetrazolium.

of the integrins, and hence antibodies to these surface molecules can be used in conjunction with flow cytometry to diagnose this deficiency. Similarly the detection of the surface expression of sLe^x is a diagnostic tool for LAD2. The ability for neutrophils from these patients to adhere to plasma-coated surfaces in microtiter plates can be measured when these cells are either treated or not treated with agonists such as TNF or fMLP. The ability to respond to complement-coated particles that are ligated to neutrophils via the CR3 receptor can also be diagnostic for LAD1. Because these cells are unable to adhere to substrates they will also show a deficiency of chemotaxis.

Chemotactic assays have now been relatively standardized and defects of chemotaxis can be identified by these assay methods. The two methods that are usually used are the technique of migration under agarose and in chemotactic chambers, developed by Boyden and referred to as the Boyden chamber (Boyden 1962), and modifications thereof (Rot 1999). In the former assay, wells are cut into agarose into which cells and a chemotactic agent such as fMLP can be applied. As the fMLP diffuses through the agarose, a chemotactic gradient is set up which attracts the cells and the distance migrated can be measured microscopically.

The Boyden chamber and related chambers consist of two compartments separated by a filter that contains pores to enable neutrophils to crawl through from one chamber toward the chemotactic agent in the other chamber. The distance moved or number of cells moved into the filter is measured to ascertain the chemotactic response. Once again fMLP is used most commonly as the chemotactic agent but others include LTB_4 and complement, e.g. C5a, IL-8.

Measurement of the phagocytic activity of the cell can be quite difficult because it is difficult to distinguish between adhered and engulfed particles. Some techniques can be rather subjective when microscopic counting of internalized particles is conducted. The particles used include zymosan (yeast), *C. albicans*, and erythrocytes. These are opsonized for promoting recognition by neutrophils. One means of distinguishing between adhered and ingested particles is to use radiolabeled *S. aureus* and then eliminate those that have not been ingested by treating with lysostaphin. A radiometric technique has also been described that takes into consideration that there is little RNA synthesis in neutrophils. In this assay, after an incubation period to allow phagocytosis to take place, [^{3}H]uridine, which is readily taken up by non-engulfed bacteria or fungi, is added to the cultures. The amount of inhibition of uridine uptake measures an index of phagocytic power. Other systems make use of erythrocytes and hypotonic lysis of nonphagocytosed erythrocytes. A flow cytometry method has also been developed which makes use of fungi or bacteria with fluorescent labels and quenching of any nonengulfed bacteria with trypan blue.

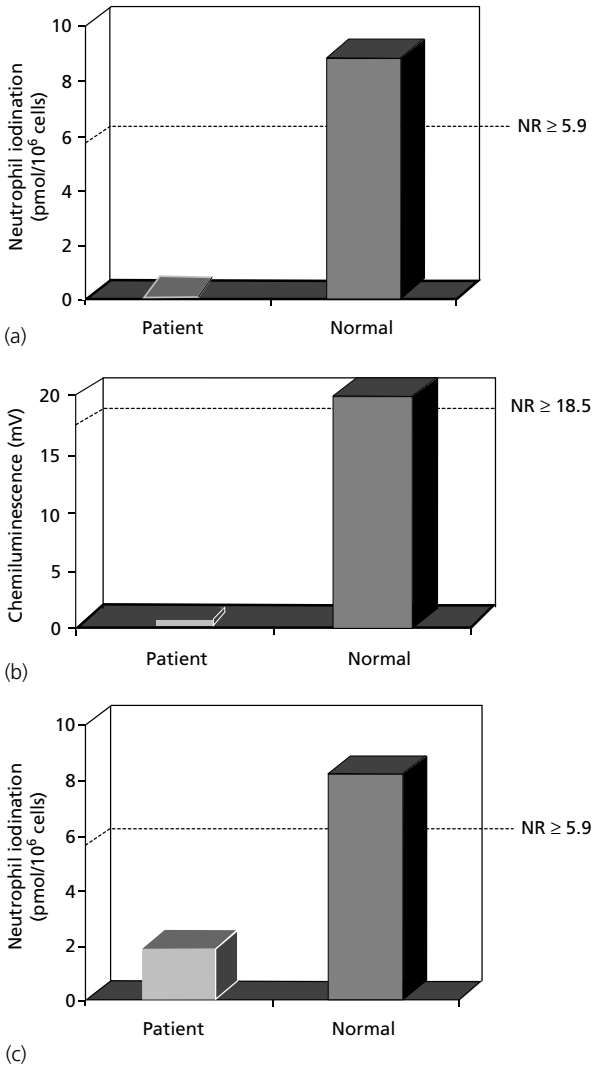

Figure 9 *The neutrophil iodination reaction in chronic granulomatous disease (CGD) and myeloperoxidase (MPO)-deficient neutrophils.* **(a)** *Lack of chemiluminescence response in neutrophils from patients with chronic granulomatous disease stimulated with formyl-methionine–leucine–phenylalanine (fMLP).* **(b)** *Poor leukocyte iodination reaction in the same cells stimulated with opsonized zymosan.* **(c)** *Depressed leukocyte iodination reaction in neutrophils from an MPO-deficient patient. NR, normal range.*

Defects in the oxidase can be assessed by a range of assays. The cells fail to undergo respiratory burst activity and hence do not produce oxygen-derived reaction species. Various assays are available for measuring O_2^- and H_2O_2. A standard assay for O_2^- is the superoxide dismutase-inhibitable cytochrome *c* reduction assay, which measures a color change that is read spectrophotometrically (Figure 9). In another system, a lucigenin-dependent chemiluminescence assay is used for measuring the superoxide produced by cells. This assay is facilitated by the used of a luminometer which dark-adapts the cells and is able to inject various components into the assay mixture.

The classic test for GGD and a detective oxidase system is the nitroblue tetrazolium (NBT) dye reduction. This is readily performed on cells adherent to microscope slides. A stimulus is used to activate the oxidase. In this reaction, the pale-yellow NBT is reduced to form a blue formazan. The cells positive for this reaction are scored microscopically. Normal cells will have more than 98 percent of the cell staining positively for NBT reduction while neutrophils from CGD patients lack staining. As a defect of the oxidase is being sought, phorbol myristate acetate (PMA) is the preferred stimulus which bypasses the surface receptor and stimulates the assembly of the oxidase by activating PKC. This excludes other possible defects such as β_2-integrin deficiencies, which can give rise to lack of activation of the oxidase because of particle adhesion defects. Then, by using opsonized zymosan in combination with PMA, defects of adhesion and ingestion can be diagnosed by the same testing system.

Flow cytometers are now readily available and a fluorescence assay that is based on the oxidation of an intracellular 2′,7′-dichlorofluorescein diacetate to the highly fluorescent 2′,7′-dichlorofluorescein can also be used to detect oxidase activity in stimulated neutrophils. Other fluorescence indicators include dihydrorhodamine 123. Both PMA and opsonized zymosan can be used to stimulate the respiratory burst.

Myeloperoxidase deficiency is the most common neutrophil disorder and various methods can be used to detect the presence or absence of MPO as well as to quantify MPO levels. This includes histochemical staining of the enzyme in cells or examining a leukocyte extract for the enzyme. A convenient method is the quantitative leukocyte iodination reaction (see Figure 9). This takes into consideration both the release of MPO and the production of H_2O_2 (i.e. oxidase activity). Thus, in conjunction with a measurement of the oxidase assay such as NBT or chemiluminescence, the assay can be a first-line screen for MPO deficiency (see Figure 9).

Neutrophil microbial killing assays are important because these represent the net effect of all the cellular components and, if the appropriate opsonin and microorganisms are chosen, this will detect most of the neutrophil defects such as LAD, MPO deficiency, NADPH oxidase defects, degranulation deficiency, and phagocytosis defects. The particles used will usually be complement-opsonized bacteria or fungi. Samples taken over the period of 1 hour for bacteria and 2 hours for fungi can be used to determine both the amount and the rate of killing, e.g. with MPO deficiency, neutrophils will show a delay in killing of *C. albicans*. For killing of bacteria, *S. aureus* is usually chosen. As this bacterium can produce H_2O_2, the lack of NADPH oxidase activity can be overcome. Thus, it is essential that the *S. aureus* used is catalase positive.

Basophils and eosinophils

EDWARD E.S. MITRE AND THOMAS B. NUTMAN

Basic biology	1	Basophilia and eosinophilia as disease markers	13
Cell trafficking	4	Role in infectious diseases	13
Cell function	7	References	17
Immunomodulatory capabilities	12		

Basophils and eosinophils are leukocytes with large cytoplasmic granules that originate from $CD34^+$ progenitor cells. Although both are present at tissue sites of inflammation in allergic and helminthic disease, basophils reside predominantly in the circulation, whereas the majority of eosinophils are found in the tissues. Both cell types have lifespans of a few days, which can be prolonged through the actions of the interleukins IL-3, IL-5, and other growth factors; there is a large overlap in the mediators that cause them to traffic from the circulation to sites of inflammation. Both cell types release multiple inflammatory mediators, with histamine being the primary effector molecule of basophils and granule proteins being the primary effector molecules of eosinophils. Basophils typically degranulate through an IgE-dependent pathway, whereas eosinophils are most often activated by cytokine–cytokine receptor interaction. Although both cells are classically considered part of the innate immune system, they also modify the adaptive immune system through the release of cytokines and chemokines. In addition, histamine released from basophils has multiple immunomodulatory effects, and eosinophils have the ability to process and present antigen. Finally, basophils and eosinophils are clearly involved in the immune response to helminth infections and play a role in HIV and respiratory virus infections.

BASIC BIOLOGY

Basophils

MORPHOLOGY

Basophils are the least common white blood cell, making up 0.5–1 percent of the circulating peripheral blood cell population and accounting for 0.33 percent of the nucleated cells in the marrow (Juhlin 1963). They have lobulated nuclei of various forms and contain multiple prominent amorphous granules that stain purple to red with blue aniline dyes (Figures 1a and 2a). This staining pattern is the result of the presence within the granules of highly sulfated proteoglycans which are often complexed to proteases, histamine, and cytokines.

GROWTH AND DIFFERENTIATION

Basophils, as well as eosinophils, mast cells, monocytes, and neutrophils, originate from pluripotential $CD34^+$ progenitor cells found in cord blood, peripheral blood, and bone marrow (Kirshenbaum et al. 1991; Metcalf 1989). Basophils and eosinophils are believed to derive from a subset of $CD34^+$ cells that are also interleukin (IL) IL-3Rα^+ and IL-5R$^+$ (Boyce et al. 1995). The existence of a common progenitor cell for eosinophils and basophils is supported by the finding of granulocytes with hybrid eosinophil/basophil phenotype in vivo in patients with chronic myelogenous leukemia (Weil and Hrisinko 1987) and in vitro in cultures of peripheral blood and bone marrow from normal human donors (Leary and Ogawa 1984; Denburg et al. 1985). There is also evidence that basophils share a common progenitor with mast cells. Traditionally, basophils have been thought to arise from a separate cell lineage than mast cells, the progenitor cells of which are $CD34^+/CD38^+$ (Kempuraj et al. 1999) or $CD34^+$/c-kit$^+/CD13^+$ (Kirshenbaum et al. 1999). Recently, however, a new monoclonal antibody (97A6 – which targets ectonucleotide pyropho-

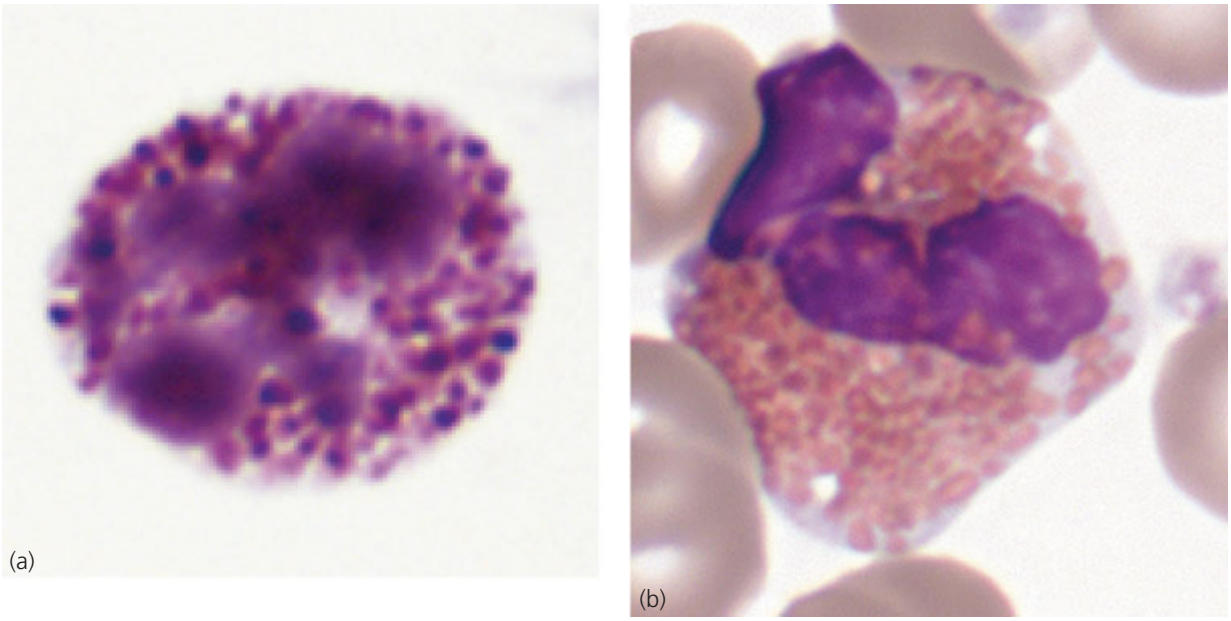

Figure 1 (a) *May–Grunïwald stain of a human peripheral blood basophil at 1000 × magnification with typical multilobulated nucleus and multiple large purple-staining granules of variable size.* **(b)** *Wright–Giemsa stain of a human peripheral blood eosinophil viewed at 1000 × demonstrating the characteristic bilobed nucleus and red-staining granules.*

sphatase/phosphodiesterase 3) has been described that is specific for mast cells, basophils, and their precursors (Buhring et al. 1999, 2001), suggesting that mast cells and basophils arise from a similar lineage.

The principal cytokine required for basophil growth and differentiation is IL-3 (Valent 1995); 9.5–50 percent of cord blood and bone marrow cells differentiated in the presence of IL-3 becomes basophils, with the remaining cells consisting of eosinophils, neutrophils, and macrophages (Saito et al. 1988). Growth of chronic myelogenous leukemia basophils, and of the human basophil-like cell line KU 812, is supported by IL-3 through high-affinity binding sites (Valent et al. 1989, 1990); moreover, humans treated with recombinant human IL-3 (rhIL-3) develop basophilia (Ganser et al. 1990). Studies with IL-3 knock-out (KO) mice have

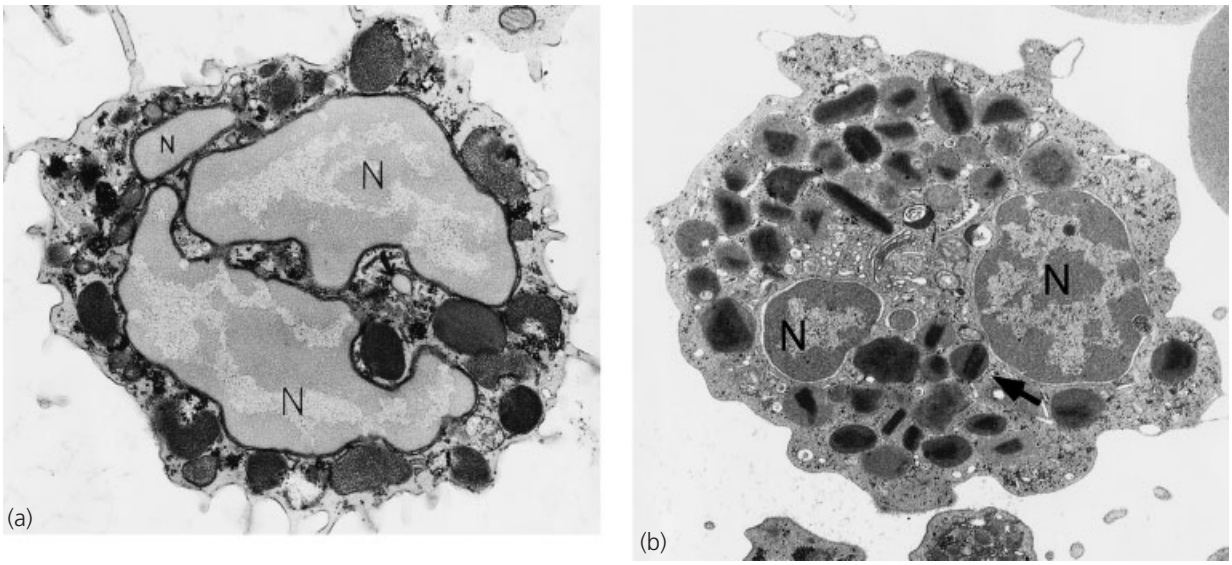

Figure 2 (a) *Electron micrograph of a human blood basophil with characteristic multilobulated nucleus (N) and numerous large secretory granules filled with electron-dense particles. Another granule type is small, rests near the nucleus, and contains homogenous, poorly electron-dense material (arrow). Focal electron-dense particles and aggregates of glycogen are present in the cytoplasm. ×77000 (With permission, Dvorak et al. 1996).* **(b)** *Electron micrograph of a human blood eosinophil with bilobed nucleus (N) and several characteristic specific granules with dense crystalloid cores (arrow). ×77000 (Image courtesy of William Riemenschneider NHLBI, NIH.)*

demonstrated that IL-3 is not required for development of baseline basophil numbers in the bone marrow and circulation, but is necessary for the enhanced basophil production seen in mouse models of helminth infection (Lantz et al. 1998).

Cytokines other than IL-3 also contribute to basophil development. Differentiation of the human basophil-like cell line KU 812 can be promoted by IL-6 and tumor necrosis factor α (TNF-α) (Nilsson et al. 1994); granulocyte–macrophage colony-stimulating factor (GM-CSF) and possibly IL-5 can cause basophil differentiation and increased production from the peripheral blood (Hutt-Taylor et al. 1988; Saito et al. 1988; Denburg et al. 1991). Although they do not have much of an effect when acting alone, nerve growth factor (NGF) and transforming growth factor β (TGF-β) can act in synergy with GM-CSF and IL-3, respectively, to enhance basophil growth (Matsuda et al. 1988; Tsuda et al. 1991; Sillaber et al. 1992).

NATURAL HISTORY

Basophils, which primarily remain in the circulation after maturation in the bone marrow, can infiltrate tissues at sites of active inflammation in parasitic diseases (Cross et al. 1987), asthma (Kepley et al. 2001), and allergy (Mitchell et al. 1982; Guo et al. 1994). The typical basophil has a relatively short lifespan, ranging from a few days to a few weeks. IL-3, IL-5, and NGF all improve the basophil lifespan in culture, with IL-3 improving viability the most (Miura et al. 2001). Whereas basophils cultured in media alone die within 3 days, basophils cultured with IL-3 have > 95 percent viability at 3 days (Miura et al. 2001). The basophil lifespan is also prolonged slightly by GM-CSF but not by IL-4, G-CSF, M-CSF (Yamaguchi et al. 1992), or stem cell factor (Dvorak et al. 1994). Basophils differentiated in vitro appear at about 1 week, peak at 3 weeks, and then decrease in number thereafter (Kirshenbaum et al. 1989). Basophils usually die through apoptosis, which can be induced by glucocorticoids (Yoshimura et al. 2001) and inhibited by IL-3 (although not by IL-5 or GM-CSF) (Zheng et al. 2002).

Eosinophils

MORPHOLOGY

Eosinophils have bilobed nuclei and large cytoplasmic granules that stain with eosin and other acidic dyes (see Figures 1b and 2b). Specific granules have dense crystalloid cores and store the major secretory effector proteins as well as various enzymes and cytokines. Another population of granules, so-called primary granules, contain Charcot–Leyden crystal protein. Smaller granules contain acid phosphatase and arylsulfatase, and non-membrane-bound organelles called lipid bodies contain arachidonic acid, 5-lipoxygenase, and cyclooxygenase (and are probably the main sites of prostaglandin and leukotriene production in the eosinophil) (Weller and Dvorak 1994). Eosinophils also have vesiculotubular structures that contain cytochrome b_{558}, a component of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that enables eosinophils to produce superoxide upon activation.

GROWTH AND DIFFERENTIATION

Like basophils, eosinophils develop in the bone marrow from pluripotent $CD34^+$ cells in approximately 1 week. Differentiation into eosinophils is primarily guided by IL-3, IL-5, and GM-CSF. Of these, IL-5 is the most powerful inducer of eosinophilopoiesis, as the usual bone marrow eosinophilia that develops in sensitized mice challenged with allergen is almost completely abrogated by treatment with anti-IL-5, yet hardly diminished by either anti-IL-3 or anti-GM-CSF (Tomaki et al. 2002). Eosinophilopoiesis is not dependent exclusively on these three cytokines, because mice that lack the IL-5 receptor (Foster et al. 1996) or the common receptor β chain for these three cytokines (Nishinakamura et al. 1995) are able to produce eosinophils, although the basal level is lower than normal and the mice are unable to increase their eosinophil counts in response to helminths or allergic challenge. Unlike IL-3 and GM-CSF, which promote the development of multiple lineages, IL-5 acts most specifically on eosinophils. IL-5 is made predominantly by type II $CD4^+$ T cells, but can also be made by natural killer (NK) cells, $CD8^+$ T cells, and eosinophils.

Eosinophilopoiesis can be inhibited by IL-12. Mice lacking IL-12 have higher bone marrow eosinophil counts than control mice (Zhao et al. 2000), and treatment of allergic mice with intrapulmonary IL-12 decreases bone marrow eosinophil counts by up to 45 percent (Rais et al. 2002). IL-12 may inhibit eosinophil production by upregulation of interferon γ (IFN-γ), because IL-12 inhibition of eosinophilopoiesis does not occur in IFN-γ KO mice (Rais et al. 2002).

NATURAL HISTORY

After differentiation, a pool of mature eosinophils remains in the bone marrow and can be rapidly released after IL-5 or eotaxin administration (Palframan et al. 1998a, 1998b). Eosinophils typically circulate for 3–26 hours in the circulation before migration into tissues, where the vast majority of eosinophils exist and where they survive for several days to weeks. In vivo studies of mice infected with *Angiostrongylus cantonensis* show that eosinophils taken from the site of infection have prolonged survival compared with that of peripheral blood eosinophils (Sugaya et al. 2001). The eosinophil lifespan is prolonged by IL-5, IL-3, and GM-CSF, each of which prevents apoptosis of eosinophils in in vitro culture systems (Simon and Blaser 1995). In the absence

of stimulating cytokines, eosinophils soon undergo apoptosis (Walsh 1997). Eosinophils survive up to 10 days in the presence of IL-5 but only up to 4 days in its absence (Yamaguchi et al. 1991); 53 percent of eosinophils cultured in vitro with IL-3 are viable at 14 days, whereas only 10 percent are viable in its absence (Rothenberg et al. 1988). After 7 days of culture with GM-CSF, 43 percent of human eosinophils remain alive, whereas most eosinophils cultured in media alone are dead (Owen et al. 1987). IL-5, IL-3, and GM-CSF most probably prolong eosinophil survival by inhibiting apoptosis by signaling through the β subunit of their receptors, which they all share. This β subunit interacts with Lyn and syk tyrosine kinases involved in anti-apoptotic signaling in eosinophils (Yousefi et al. 1996).

Eosinophil survival can also be prolonged by IL-15 (probably through induction of autocrine GM-CSF production by eosinophils) (Hoontrakoon et al. 2002), TNF-α (Valerius et al. 1990), nitric oxide (Beauvais et al. 1995), and engagement of CD40 (Bureau et al. 2002). Although IFN-γ and IFN-α are generally considered capable of prolonging eosinophil survival (Valerius et al. 1990), one study showed that interferons diminished eosinophil survival (Morita et al. 1996).

Eosinophils usually die through apoptosis. This occurs in the absence of activating cytokines and is most probably induced through events mediated by the Fas receptor (CD95) (Matsumoto et al. 1995), which eosinophils express on their surface (Druilhe et al. 1996). Apoptosis of eosinophils can also be induced by glucocorticoids (Meagher et al. 1996), TNF-α (Fujihara et al. 2002), TGF-β_1 (Atsuta et al. 1995), and through ligation of CD69, a type II membrane antigen expressed on cytokine-stimulated eosinophils (Walsh et al. 1996). The recent finding that CD69 expression on eosinophils of patients with asthma increases after stimulation with a specific inhalation challenge suggests that CD69 may play a role in a negative feedback loop in eosinophilia (Pignatti et al. 2002).

Eosinophils that have undergone apoptosis are ingested by macrophages using macrophage surface proteins CD36 and $\alpha_v\beta_3$ (Stern et al. 1996), thus preventing unwanted deleterious release of toxic intracellular products upon eosinophil death.

CELL TRAFFICKING

Trafficking of basophils and eosinophils from the peripheral circulation to sites of inflammation occurs through a multistep process (Springer 1994), with leukocytes rolling on endothelial cells through binding of selectins, firmly adhering to endothelium via integrins, transmigrating through the endothelial cell layer by diapedesis, and finally proceeding to sites of inflammation through the effects of chemotactic agents. The exact mechanisms by which this occurs have been studied in greater detail in eosinophils than in basophils. As a result of the large number of adhesion and chemotaxis factors common to both cell types (Tables 1 and 2), it is likely that trafficking of basophils and eosinophils is quite similar. The extent of the overlap between the pathways of basophil and eosinophil recruitment and the extent to which these cell types are recruited independently of one another are areas of active investigation (Bochner and Schleimer 2001). Factors that alter expression of adhesion molecules and the relative importance of different chemotactic factors with regard to each cell type are discussed below.

Basophils

BASOPHIL ADHESION

Expression of basophil adhesion molecules is modulated by several factors. Pretreatment with IL-1 and TNF-α (Bochner et al. 1988), as well as FcεR1 aggregation (Bochner et al. 1989), enhances the ability of basophils to bind to endothelial cells, probably by upregulating CD18 on basophils. IL-3 increases basophil adhesiveness to endothelial cells, possibly by increasing CD11b – a molecule that can bind to intercellular adhesion molecule 1 (ICAM-1), fibrinogen, and complement component C3bi (Bochner et al. 1990) – on basophils. In addition to CD11b, basophil activation also increases surface expression of CD11c and αd, two other β integrins (Bochner 2000).

The type 2 cytokines IL-4 and IL-13 increase the ability of basophils and eosinophils to bind to endothelial cells by increasing endothelial cell expression of vascular cell adhesion molecule 1 (VCAM-1), to which basophils and eosinophils, but not neutrophils, can bind (Columbo et al. 1992; Bochner et al. 1995).

CHEMOTAXIS

Multiple factors – including cytokines, chemokines, complement components, and lipid products – serve as basophil chemoattractants. Of the CC chemokines, RANTES and monocytic chemotactic peptide (MCP-3) 3 have the greatest ability to attract basophils, followed by MCP-1 and macrophage infectivity potentiator 1α (MIP-1α) (Dahinden et al. 1994). In terms of the effects of the CC chemokines on basophils, RANTES acts mostly as a chemoattractant, MCP-1 as an inducer of basophil degranulation, and MCP-3 as a combination, serving as both a strong chemoattractant and an inducer of basophil degranulation (Rot et al. 1992; Dahinden et al. 1994). MCP-2, another CC chemokine, is also chemoattractive for basophils (Weber et al. 1995). Stromal cell-derived factor 1α (SDF-1α), a CXC chemokine that is the only known ligand for CXCR4, has been shown to recruit basophils with even greater potency than RANTES and MCP-1 (Jinquan et al. 2000). Of the

Table 1 *Basophil and eosinophil adhesion molecules and chemotaxis factors*

Adhesion molecules	Ligands	Adhesion molecule expression by Basophils	Eosinophils
Integrins			
β_1 *(VLA family)*			
$\alpha_4\beta_1$ (CD49d/CD29)	VCAM-1, fibronectin	+	+
$\alpha_5\beta_1$ (CD49e/CD29)	Fibronectin	+	+
$\alpha_6\beta_1$ (CD49f/CD29)	Laminin	–	+
β_2 *family*			
LFA-1 (CD11a/CD18)	ICAM-1, -2, -3	+	+
Mac-1 (CD11b/CD18)	C3bi, ICAM-1, fibronectin	+	+
P150,95 (CD11c/CD18)	C3bi, others	+	+
αd (αd/CD18)	ICAM-3, VCAM-1	+	+
β_7 *family*			
$\alpha_4\beta_7$	MAdCAM-1, VCAM-1, fibronectin	+	+
Ig gene superfamily			
ICAM-1 (CD54)	LFA-1, Mac-1	+	+
ICAM-3 (CD50)	LFA-1	+	+
PECAM-1 (CD31)	CD31	+	+
ICAM-2 (CD102)	LFA-1	+	–
Selectins			
L-Selectin (CD62L)	GlyCAM-1, CD34, MAdCAM-1	+	+
PSGL-1 (CD162)	P-Selectin	+	+
Sialyl Lewis-X (CD15s)	E-Selectin, P-selectin	+	+
Sialyl-dimeric Lewis-X	E-Selectin	+	+
Lewis-X (CD15)	P-Selectin	–	+
Others			
Pgp-1 (CD44)	Hyaluronic acid	+	+
Siglec-8	Sialic acid	+	+

Table 2 *Basophil and eosinophil adhesion molecules and chemotaxis factors*

Chemotaxis factors	Predominant recepter	Recepter expression by Basophils	Eosinophils
Chemokines			
MIP-1α, RANTES, MCP-2[a]	CCR1	+	+
Eotaxin, MCP-3, MCP-4, RANTES	CCR3	+	+
SDF-1α	CXCR4	+	+
MCP-1	CCR2	+	–
MIP-3α	CCR6	+	–
Cytokines			
IL-3	IL-3R	+	+
IL-5	IL-5R	+	+
IL-8	CXCR1, CXCR2	?	?
GM-CSF	GM-CSFR	+	+
TNF-α	TNF-αR	–	+
Others			
C3a	C3aR	+	+
C5a	C5aR (CD88)	+	+
fMLP	fMLPR	+	+
PAF	PAFR	+	+
Prostaglandin D_2	CRTH1	+	+
Leukotriene B_4	LTB_4R	?	+

See text for abbreviations.
a) MCP-2 can also use CCR2B and CCR3 as functional receptor.

cytokines, IL-3 and GM-CSF are strong basophil chemoattractants, and IL-5 and IL-8 are weak ones (Tanimoto et al. 1992; Yamaguchi et al. 1992).

Eotaxin, eotaxin-2, and eotaxin-3, which are usually considered primarily as eosinophil chemoattractive proteins, are also potent basophil chemoattractants (Yamada et al. 1997; Dulkys et al. 2001; Menzies-Gow et al. 2002). Other basophil chemoattractants include the complement components C3a and C5a, leukotriene B_4 (LTB_4), and platelet-activating factor (PAF) (Lett-Brown et al. 1976; Tanimoto et al. 1992). Recently, prostaglandin D_2 has been shown to induce migration of basophils and eosinophils through the CRTH2 receptor (Hirai et al. 2001).

The ability of basophils to migrate toward chemoattractants C5a, IL-3, and IL-8 is inhibited by dexamethasone (Yamaguchi et al. 1994).

Eosinophils

ADHESION

Recruitment of eosinophils out of the circulation begins with binding of VLA-4 ($\alpha_4\beta_1$) and selectins on eosinophils to VCAM-1 and E-selectin present on activated endothelial cells (Sriramarao et al. 1994, 2000; Ulfman et al. 1999). The ability to bind to VCAM-1, in particular, allows eosinophils and basophils to be selectively recruited from the circulation, because neutrophils lack VLA-4 (Walsh et al. 1991).

Once tethered, eosinophils can be acted upon by inflammatory mediators to upregulate integrins and other cell adhesion molecules to enable firm adhesion. IL-8, MCP-1, C3a, C5a, and PAF can all induce activation-dependent adhesion of rolling eosinophils, probably through upregulation of β_2-integrins that can bind to ICAM-1 on endothelial cells (Discipio et al. 1999; Gerszten et al. 1999; Ulfman et al. 2001; Broide 2002). Although CD11b–CD18 binding to ICAM-1 is considered important for firm adhesion, it is not necessary for tissue eosinophilia, because patients with CD18 deficiency still have eosinophils present in inflamed tissues (Anderson et al. 1985). After firm adhesion, cells then diapedese across the endothelial wall. In addition to inducing firm adhesion, C5a has been shown to enable eosinophils to migrate across the vascular endothelium (Discipio et al. 1999). Once across, leukocytes migrate through tissues under the guidance of chemoattractants.

Eosinophil-binding molecules are affected by numerous factors. As with basophils, IL-4 increases selective recruitment of eosinophils from the circulation by specifically upregulating expression of VCAM-1 on endothelial cells and enhancing VLA-4/VCAM-1 binding (Moser et al. 1992; Schleimer et al. 1992). IL-4, as well as TNF-α, has also been shown to upregulate VCAM-1 expression by lung fibroblasts (Sabatini et al. 2002). TNF-α also causes lung fibroblasts to increase ICAM-1 expression and to release the eosinophil chemoattractants MCP-1 and eotaxin. IL-4 and IL-13 have been shown in a mouse model of *Onchocerca volvulus* keratitis to recruit eosinophils to the cornea through upregulation of ICAM-1 expression on limbal vascular endothelial cells (Berger et al. 2002).

Other cytokines that can affect eosinophil adhesion include IL-3 and GM-CSF, which were shown to upregulate expression of VLA-4 and VLA-5 on eosinophils in a study of patients infected with *Onchocerca volvulus* (Brattig et al. 1995). This study also found that infective onchocerca larvae had fibronectin deposited on their surface, raising the possibility that eosinophils bind directly to helminths through fibronectin, a known ligand for VLA-4 and VLA-5.

Together, TNF-α and C5a increase eosinophil attachment to human bronchial epithelial cells threefold through upregulation of $\alpha_5\beta_1$ integrin, which appears to bind fibronectin (Burke-Gaffney et al. 2002).

In a sheep model of trichostrongylus infection, eosinophils at sites of helminth infection exhibit increased CD18 expression compared with circulating eosinophils (Stevenson et al. 2001). One agent that has been shown to increase CD18 and CD11b expression on eosinophils is leukotriene D_3 (LTD_3), which probably does so through the cysLT-1 receptor and β_2 integrin (Nagata et al. 2002).

The eotaxin proteins can also affect eosinophil adhesion. Eotaxin-1 has been shown to enhance binding of eosinophils to VCAM-1 (Kitayama et al. 1997). Eotaxin-2 appears to cause eosinophils to shift from VCAM-1 to ICAM-1 adhesion, possibly acting to enable firm adhesion after eosinophils have been tethered (Tachimoto et al. 2002). Eotaxin-2 also plays a role in eosinophil deadhesion (Tachimoto et al. 2000), whereas eotaxin-3 induces transmigration of eosinophils across the endothelium (Cuvelier and Patel 2001).

CHEMOTAXIS

Eotaxin

Initially isolated from the bronchiolar fluid of sensitized guinea pigs, eotaxin-1 is an 8- to 9-kDa protein with an amino acid sequence very similar to that of the CC chemokines MCP-1, MCP-2, and MCP-3 (Jose et al. 1994). Eotaxin is a powerful and specific eosinophil chemoattractant (Jose et al. 1994; Garcia-Zepeda et al. 1996). It acts by binding to CCR3, which is also the receptor for RANTES, MCP-2, MCP-3, and MCP-4 (Marleau et al. 1996; Alkhatib et al. 1997; Heath et al. 1997), and its production probably occurs via activation of the transcription factor NF-κB (Jedrzkiewicz et al. 2000). The importance of eotaxin and other CC chemokines in eosinophil recruitment is underscored by the finding that CCR3 KO mice fail to recruit eosinophils to the small intestine and skeletal muscle even after

infection with *Trichinella spiralis* (Gurish et al. 2002). Eotaxin can be made by pulmonary epithelial cells, because eotaxin mRNA is detectable in human epithelial cell lines after stimulation with TNF-α and IL-1β (Lilly et al. 1997). Production of eotaxin-1 by human airway fibroblasts is increased by TGF-β and IL-13 (Wenzel et al. 2002). IL-4, another type 2 cytokine, has differential effects on the production of eotaxin, upregulating its production by human lung epithelial cells and downregulating its production by peripheral blood mononuclear cells (PBMCs) (Nakamura et al. 2001). This differential effect probably serves to increase eosinophil recruitment out of the peripheral circulation and into the tissues.

Mice lacking the eotoxin gene have lower baseline levels of peripheral blood eosinophils and less eosinophilia in response to antigen challenge than normal mice (Rothenberg et al. 1997; Matthews et al. 1998). The findings that plasma eotaxin levels are significantly elevated in patients with acute asthma compared with age-, sex-, and ethnicity-matched patients with stable asthma (Lilly et al. 1999) and that bronchoalveolar lavage (BAL) levels of eotaxin increase after segmental allergen challenge (Lilly et al. 2001) suggest that eotaxin contributes to the eosinophilia in asthma and allergic diseases of humans. Intradermal injection of eotaxin and eotaxin-2 into atopic and nonatopic human volunteers results in infiltration of eosinophils, basophils, neutrophils, and macrophages, as well as in histological changes consistent with mast cell degranulation (Menzies-Gow et al. 2002).

As discussed in the previous section, eotaxin also mediates eosinophil adhesion. Notably, the ability of eotaxin to upregulate CD11b is three times greater in IL-5 transgenic mice than in normal mice, a finding that suggests synergy between eosinophil-specific cytokines such as IL-5 and chemokines in terms of inducing eosinophil aggregation (Kudlacz et al. 2002). Glucocorticoids, which suppress eosinophilia, have been shown to suppress eotaxin mRNA expression (Lilly et al. 1997).

Eotaxin-2 and eotaxin-3 (so named because of functional, not structural, similarities to eotaxin) are other CC chemokines that mediate their effects through CCR3. They serve as chemoattractants for both eosinophils and basophils and have been shown to have similar efficacy for inducing calcium flux, activating Gi proteins, and inducing superoxide anion generation as eotaxin (Forssmann et al. 1997; Dulkys et al. 2001; Badewa et al. 2002).

Interleukin 5

In addition to supporting differentiation and growth of eosinophils, IL-5 is a strong eosinophil chemoattractant (Lampinen et al. 2001). Although IL-5 does not appear to regulate baseline eosinophil blood counts, as IL-5 KO mice have normal basal peripheral eosinophil counts (Kopf et al. 1996), IL-5 is one of the major factors responsible for recruiting eosinophils into tissues. IL-5 KO mice sensitized to ovalbumin do not develop the eosinophilia, hyperreactivity, and lung damage that normal sensitized mice do after allergen challenge (Foster et al. 1996). Overexpression of IL-5 in transgenic mice results in increased numbers of eosinophils in the gastrointestinal mucosa compared with those in control mice (Mishra et al. 2002), and treatment of patients with asthma with monoclonal anti-IgE antibody results in significant decreases in sputum eosinophils (Fahy et al. 1997).

Although important, IL-5 is not an absolute requirement for the recruitment of eosinophils into tissues, because pulmonary eosinophilia with morphologically normal eosinophils occurs in the lungs of IL-5KO mice infected with pneumonia virus of mice (PVM) to the same degree as in those of control mice (Domachowske et al. 2002).

Other chemotaxis factors

Many other factors have been shown to serve as eosinophil chemoattractants, including the complement components C3a and C5a, the CC chemokines MCP-2, MCP-3, and RANTES, and the cytokines GM-CSF, IL-2, IL-3, and IL-8 (Resnick and Weller 1993; Noso et al. 1994; Schweizer et al. 1994; Weber et al. 1995; Discipio et al. 1999). It has been shown that LTB_4 and PAF can induce eosinophil chemotaxis (Klein et al. 2001; Oliveira et al. 2002), and TNF-α has been show to recruit eosinophils in ulcerative colitis (Lampinen et al. 2001). Ligation of SDF-1α to CXCR4 also induces eosinophil migration (Nagase et al. 2000). Although not directly acting on eosinophils, intranasal delivery of IL-13 into mice causes lung and airway eosinophilia by increasing IL-5 and eotaxin production (Pope et al. 2001). Finally, it has been shown that eosinophils can accumulate at sites of helminth infection even in mice lacking B and T cells, suggesting that eosinophils may be directly recruited by some helminth molecule or some factor released by normal tissue in response to a helminth infection (Shinkai et al. 2002).

CELL FUNCTION

Basophils

As a result of their ability to bind IgE, individual basophils can specifically recognize and be activated by many different antigens. Activation of basophils causes release of preformed and newly synthesized inflammatory mediators that play important roles in vascular reaction, exudation, leukocyte accumulation, and wound healing. In addition, basophils have the ability to produce and release cytokines and to phagocytose particles.

ACTIVATION

IgE-mediated activation

The most important molecules for basophil function are their high-affinity IgE receptors (FcεR1s). These receptors are highly specific for IgE and bind them in a 1:1 ratio, with the Cε3 domain of the Fc portion of the IgE antibody serving as the principal binding site for FcεR1 (Weetall et al. 1990). When a multivalent antigen binds to several IgE molecules, the receptors aggregate and initiate cell activation, stimulating mediator generation and release (Turner and Kinet 1999). Basophil degranulation occurs very quickly, with crosslinking of IgE causing half-maximum histamine release from basophils in 7 minutes (Kuna et al. 1992).

Although maximal histamine response occurs when about 10 percent of the FcεR1 is aggregated, aggregation of as few as 100 receptors is enough to activate a basophil (Menon et al. 1984). As basophils can express well over 200 000 FcεR1s per cell (MacGlashan et al. 1997), a single basophil can theoretically hold enough different IgE molecules to enable that basophil specifically to recognize and be activated by well over 1000 antigens.

FcεR1 upregulation on basophils is mediated by the interaction of IgE with FcεR1 (MacGlashan et al. 1999). As a result of this, the number of FcεR1s expressed on basophils is proportional to the amount of IgE in the serum (MacGlashan et al. 1997). IL-3 and IL-5, but not NGF, also probably induce FcεR1 upregulation, because they have been shown to induce FcεR1β mRNA expression in basophils in culture in vitro (Miura et al. 2001).

Human FcεR1 can be expressed as a tetrameric ($\alpha\beta\gamma_2$) or trimeric ($\alpha\beta_2$) structure (Kinet 1999). There is a large range in the ratio of the FcεR1 α:β subunits in basophils from different human donors (Saini et al. 2001). As the β subunit of FcεR1 amplifies IgE-triggered signaling (Lin et al. 1996; Dombrowicz et al. 1998) and increases surface FcεR1 expression (Donnadieu et al. 2000), the finding of different FcεR1β:FcεR1α ratios suggests that basophil responsiveness is modulated in part by changes in this ratio.

In addition to FcεR1, human basophils also express FcγRIIb, a low-affinity IgG receptor. In vitro studies using human basophils have shown that co-aggregation of FcγRIIb and FcεR1 molecules decreases IgE-dependent activation (Daeron et al. 1995).

Non-IgE activation

Basophils can be activated by a number of substances through IgE-independent mechanisms. These factors, known as histamine-releasing factors, include complement proteins, human histamine-releasing factor (HRF), chemokines, cytokines, substance P, PAF, contrast media, ionophores, opiates, the bacterial peptide formyl-methionine-leucine-phenylalanine (f-Met-Leu-Phe or fMLP), and HIV glycoprotein 120.

The complement proteins C3a, C4a, and C5 cause basophil as well as mast cell degranulation (Schulman et al. 1988; Bischoff et al. 1990b). They may have a role in anaphylactoid reactions and are therefore known as anaphylatoxins. It has been suggested that anaphylatoxins may be activated in immune complex-mediated diseases, reactions to iodinated contrast media, and reactions to dialysis tubing. C3a requires the presence of IL-3 or GM-CSF to enable basophils to release histamine (Bischoff et al. 1990b). In addition to histamine release, C5a in the presence of IL-3 can cause long-lasting release of leukotriene C_4 (LTC_4), IL-4, and IL-13 by continuous signaling through the C5a receptor (Eglite et al. 2000).

Histamine-releasing factor (p23) is made by lymphocytes of atopic children and causes histamine and IL-4 release from a subset of basophils in patients with allergy (MacDonald et al. 1995; Schroeder et al. 1996). Initially believed to act through IgE, it has recently been shown to activate basophils in an IgE-independent manner, although its basophil receptor has yet to be identified (Wantke et al. 1999).

Of the CC chemokines, MCP-1 and MCP-3 are the most potent HRFs described (Dahinden et al. 1994). MCP-1 has been shown to be equivalent to IgE and C5a in its ability to cause basophils to degranulate, and it induces histamine release from basophils within 30 seconds (Alam et al. 1992; Kuna et al. 1993). Other CC chemokines that induce basophils to release histamine include MCP-2, RANTES, and MIP-1α (Alam et al. 1994; Dahinden et al. 1994). Of interest, although it is a weak inducer of basophil degranulation, MCP-2 also causes basophils not pretreated with IL-3 to lose their ability to be degranulated by MCP-1 and MCP-3, suggesting that MCP-2 may act as a functional inhibitor of MCP-1 and MCP-3 (Weber et al. 1995). SDF-1α, a CXC chemokine, induces histamine release from basophils as well as MCP-1 does (Jinquan et al. 2000).

Other less potent basophil activators include fibroblast-induced cytokine (Alam et al. 1994), MIP-1α, connective tissue-activating peptide III (CTAPIII), secretory IgA (Iikura et al. 1998), neutrophil-activating peptide-2 (NAP-2) (Kuna et al. 1993), and stem cell factor (Columbo et al. 1992). IL-18, a proinflammatory cytokine that activates NK cells and Th1 responses, induces basophils to release histamine, IL-4, and IL-13 when co-cultured with IL-3 (Yoshimoto et al. 1999). When IL-18 is given with IL-12, however, it inhibits IgE-triggered histamine activation (Yoshimoto et al. 1999).

Degranulation

Basophils release granule contents in two different ways. Anaphylactic degranulation (AND), the typical way in which basophils degranulate after IgE-mediated activation, occurs through granule-to-plasma membrane fusion and allows for very rapid release of large amounts of

granule materials (Dvorak et al. 1980). Piecemeal degranulation (PMD), on the other hand, occurs through trafficking of small vesicles from granules to the plasma membrane and results in a slow, piecemeal loss of granule contents (Dvorak et al. 1976). The most effective trigger for AND is anti-IgE (then MCP-1, then recombinant HRF or rHRF), whereas rank orders for PMD and granule-vesicle attachments are MCP-1 > anti-IgE > rHRF (Dvorak et al. 1996). Although morphologically they appear very different, AND and PMD actually represent anatomical extremes of a continuum of basophil degranulation, because, at very high rates of PMD, vesicles form into tubules by vesicle-to-vesicle fusions, allowing for direct granule-to-plasma membrane fusion, leading to the morphological release pattern termed AND (Dvorak et al. 1991).

Activation markers

CD63 has been the most commonly used marker of basophil activation. IgE-dependent activation of basophils is associated with upregulation of CD63, and the kinetics of this upregulation parallel those of histamine release from basophils (Knol et al. 1991). Increased expression of CD63 on basophils as detected by flow cytometry after in vitro allergen challenge correlates strongly with in vitro assays of histamine and LTC_4, release and has been shown to correlate with a history of allergy to both pollen (Paris-Kohler et al. 2000) and hymenoptera venom (Sainte-Laudy et al. 2000). In addition to CD63, activated basophils also upregulate several β_2-integrins (Bochner 2000).

As CD63 and integrins are not specific only for basophils, studies for other markers of activation are being actively pursued. One possible candidate is E-NPP3 (CD203c), a type II transmembrane protein exclusively expressed on basophils, mast cells, and their $CD34^+$ precursor cells (Buhring et al. 1999, 2001). E-NPP3 has recently been shown to be upregulated on peripheral blood basophils from sensitized individuals after exposure to antigen (Hauswirth et al. 2002).

Degranulation potentiators

Major potentiators of basophil degranulation include IL-3, IL-5, GM-CSF, mast cell growth factor (c-kit ligand), and NGF (Bischoff and Dahinden 1992; Kuna et al. 1993). Although none of these by itself induces basophil degranulation, they all potentiate the effects of factors that cause basophil degranulation. IL-5 enables NAP-1 and C3a to cause basophils to degranulate (Bischoff et al. 1990a) and primes basophils for IgE-dependent histamine release (Kuna et al. 1993). The ability of IL-5 to potentiate the basophil response to C5a is unclear, with studies showing both increased degranulation in response to C5a (Bischoff et al. 1990a) and no change (Miura et al. 2001). IL-3 enables IL-8 and RANTES to induce basophil degranulation (Fureder et al. 1995) and enables C5a-induced LTC_4 generation (Miura et al. 2001). Secretory IgA causes degranulation only after basophils have been exposed to IL-3, IL-5, or GM-CSF, suggesting that the intracellular signaling that primes the basophil for degranulation occurs through the shared β chain of these cytokine receptors (Iikura et al. 1998).

Other factors that potentiate IgE-mediated histamine release from basophils include recombinant human stem cell factor, IL-1α, IL-1β, mast cell growth factor (c-kit ligand), and insulin-like growth factor II (Massey et al. 1989; Columbo et al. 1992; Kuna et al. 1993).

IL-8 inhibits CTAPIII- and IL-3-dependent histamine release from basophils, although it does not inhibit anti-IgE- or fMLP-induced basophil degranulation (Kuna et al. 1991).

EFFECTOR MOLECULES

Basophils release both preformed and newly synthesized inflammatory mediators (Table 3). Preformed inflammatory mediators include histamine, chondroitin sulfates, neutral protease, elastase, β-glucuronidase, major basic protein, cathepsin G-like enzyme, Charcot–Leyden crystal protein, tryptase, chymase, and carboxypeptidase. Basophils also store basogranulin, the function of which is unknown, and IL-4. Factors that basophils synthesize on activation include LTC_4, PAI-1, IL-4, IL-13, and MIP-1α.

Histamine

Basophils are the predominant source of histamine in human peripheral blood (Porter and Mitchell 1972).

Table 3 *Basophil effector molecules*

Basophil effector molecules
Preformed inflammatory mediators
Histamine
Chondroitin sulfates
Neutral protease with bradykinin-generating activity
Elastase
β-Glucuronidase
Major basic protein
Cathepsin G-like enzyme
Charcot–Leyden crystal protein
Tryptase
Chymase
Carboxypeptidase A
Factors produced upon basophil activation
Leukotriene C_4
Plasminogen-activator inhibitor 1
Cytokines
IL-4 (preformed and *de novo* synthesis on activation)
IL-13 (*de novo* synthesis on activation)
Chemokines
MIP-1α (*de novo* synthesis on activation)

Histamine is made from histidine through the action of histidine carboxylase (Bauza and Lagunoff 1981). Circulating basophils have an average concentration of 1 pg histamine per basophil (Schulman et al. 1983; Fox et al. 1985). Histamine binds to the carboxyl groups of proteins and proteoglycans in secretory granules through ionic forces. During degranulation, histamine dissociates from the proteoglycan–protein complex by cation exchange with extracellular sodium at neutral pH. Histamine probably acts close to its site of release, because it is degraded into either methylhistamine or imidazole acetic acid within minutes of release. Histamine affects cells through its interactions with cell-specific H_1-, H_2-, and H_3-receptors (Black et al. 1972; Arrang et al. 1987). H_1-receptors induce vascular permeability, dilate arterioles, and stimulate intestinal and bronchial smooth muscle contraction. H_2-receptors stimulate gastric acid production by parietal cells, increase mucus secretion, cause endothelial cells to release prostacyclin (PGI_2 – a potent inhibitor of platelet aggregation), and modulate the immune response by inhibiting secretion from cytotoxic lymphocytes as well as neutrophils and basophils. H_3-receptors modulate neuroconduction by affecting neurotransmitter release in the central and peripheral nervous systems. Histamine also has specific immunomodulatory effects that are discussed below.

Other effector molecules

The effects of LTC_4 overlap significantly with those of histamine, because it causes smooth muscle contraction, increased vascular permeability, and mucus secretion. As it is not preformed, LTC_4 is released several hours after basophil activation and, thus, is a contributor to the late-phase response seen in allergic reactions. MIP-1α is a potent inflammatory mediator that stimulates further histamine release, causing a positive feedback loop of basophil degranulation (Li et al. 1996b).

C5a stimulation of the basophil cell line KU 812 results in production of plasminogen activator inhibitor-1, suggesting that basophils may play a role in the modulation of fibrinolysis (Wojta et al. 2002). Basogranulin is a recently identified basic protein that appears to be unique to basophils, is located in secretory granules, and is secreted (McEuen et al. 1999, 2001). Its physiological role is as yet undetermined.

Eosinophils

Upon activation, eosinophils migrate towards chemoattractants, release stored granules, and produce reactive oxygen metabolites. Eosinophils can also phagocytose foreign antigens and other materials, but do not do so as efficiently as neutrophils.

ACTIVATION

Non-Ig-mediated activation

Eosinophils are predominantly activated by non-Ig-dependent mechanisms. IL-3, IL-5, and GM-CSF, in addition to prolonging eosinophil survival, can all activate eosinophils (Owen et al. 1987; Rothenberg et al. 1988; Yamaguchi et al. 1988). In addition to its role as an eosinophil chemoattractant, eotaxin also activates eosinophils, causing calcium mobilization, production of reactive oxygen species, and upregulation of CD11b through pertussis-sensitive signaling pathways (Tenscher et al. 1996). SDF-1α, through ligation of CXCR4, also causes intracellular calcium fluxes in eosinophils (Nagase et al. 2000).

Eosinophils have receptors to many other cytokines, including IL-1α, IL-2, IL-4, IL-16, stem cell factor (c-kit), TNF-α, IFN-α, and IFN-γ, although the exact effects of these cytokines on eosinophils are not yet known.

In addition to responding to signals made by other cells, eosinophils may be able to respond directly to pathogens. While eosinophils have been shown to express mRNA for Toll-like receptors 1, 2, 4, 7, 9, and 10 (Plotz et al. 2001; Nagase et al. 2003), the functional significance of these receptors on eosinophils remains unclear. While an initial study found that LPS was able to activate eosinophils (Plotz et al. 2001), two subsequent studies have found no effect of LPS on eosinophils (Sabroe et al. 2002; Nagase et al. 2003). Interestingly, R-848, a ligand of TLR7 and TLR8, has been demonstrated to prolong survival and induced superoxide generation in eosinophils (Nagase et al. 2003). These data suggest that eosinophils have the ability to directly respond to pathogens.

Ig-mediated activation

Eosinophils have both high-affinity FcεRI and low-affinity FcεRII IgE receptors on their surface. One study showed that binding of IgE to FcεRI mediated the release of eosinophil peroxidase (EPO) from activated eosinophils (Khalife et al. 1986). A more recent study, however, showed that eosinophils have almost no surface expression of FcεRI (Seminario et al. 1999). Rather, eosinophils contain large quantities of FcεRIα (but no FcεRIβ) intracellularly and release this into the supernatant (Seminario et al. 1999). As FcεRIα binds to IgE, extracellular release of FcεRIα may serve as a way to inhibit IgE-mediated events by binding up free IgE.

Eosinophils express both IgA and IgG receptors on their surface. Of the IgG receptors, eosinophils primarily express FcγRII (CDw32), the low-affinity IgG receptor, although they also express small amounts of FcγRI (CD64), a high-affinity IgG receptor, and can express FcγRIII after exposure to IFN-γ. Crosslinking of either the IgG or IgA receptors stimulates rapid eosinophil

degranulation (Abu-Ghazaleh et al. 1989; De Andres et al. 1997; Motegi and Kita 1998), but these processes also cause the eosinophils to die and may not be physiological (Weiler et al. 1996). Thus, the role IgG and IgA receptors play in human eosinophil function remains unknown.

Degranulation

Unlike basophils, the exact mechanisms by which eosinophils undergo degranulation have not yet been elucidated. Electron microscopic analysis suggests that eosinophilic granules release their contents into small vesicles that transport them to and release them at the cell surface, akin to piecemeal degranulation in basophils (Dvorak and Weller 2000; Karawajczyk et al. 2000). In a mouse model of Nippostrongylus infection, it has been shown that, although not necessary for eosinophil accumulation at sites of helminth infection, $CD4^+$ T cells are required to enable eosinophil degranulation (Shinkai et al. 2002). The signal transmitted by $CD4^+$ T cells to cause eosinophil degranulation in this model is not known, but even $CD4^+$ T cells deficient in IL-4, IL-13, and the signal-transducing element Stat6, were able to mediate degranulation (Shinkai et al. 2002).

Once activated, eosinophils take on characteristic morphological changes with generation of cytoplasmic vacuolizations, fewer specific granules, and increased numbers of lipid bodies. Activated eosinophils are less dense and more metabolically active than unstimulated eosinophils. These hypodense eosinophils have been described in both allergic and parasitic diseases and exhibit increased surface expression of several proteins, including CD25, CD69, HLA-DR, ICAM-1, FcγRIII, and β_2-integrins (Mawhorter et al. 1996; Bochner 2000). To date, however, no unique marker of eosinophil activation has been described.

EFFECTOR MOLECULES

Effector molecules that eosinophils release include granule proteins, Charcot–Leyden crystal protein, lipid mediators, and enzymes (see Table 4), all of which are released into the extracellular space upon activation via degranulation.

Major granule proteins

Major granule proteins include major basic protein (MBP), EPO, eosinophil-derived neurotoxin (EDN), and ECP. All are located in specific granules, have markedly basic isoelectric points, and have a broad range of direct in vitro toxicity against many organisms (including helminths) and normal cells. MBP, so named because of its predominance in specific granules, is located in the central core of the specific granule, whereas the others are found in the matrix of the granule around the core. Although MBP can be found in low amounts in basophils (and EDN and ECP can be found in neutrophils) (Sur et al. 1998), eosinophils are the primary source of these proteins. In addition to its direct cytotoxic effects, MBP induces histamine release from basophils and mast cells, and superoxide production from neutrophils (Moy et al. 1990).

chloride to hypohalous acids. EDN and ECP are ribonuclease A superfamily members; however, it is not clear what role their enzymatic ability serves, because the cytotoxic activity of ECP does not require its ribonuclease activity (Rosenberg 1995). EDN, named because of its neuropathic effect on rabbits, has never been shown to be neurotoxic for humans.

Charcot–Leyden crystal protein

Located in primary granules (Dvorak et al. 1988), Charcot–Leyden crystal (CLC) protein makes up 7–10 percent of the eosinophil total protein. CLC is a lysophospholipase, which suggests that eosinophils have a role in lipid and membrane metabolism (Weller et al. 1984). X-ray crystallography of CLC shows a structural similarity to galectins (β-galactoside-binding proteins) (Leonidas et al. 1995). CLC is able to bind specifically to β-galactoside sugars, but a natural ligand for CLC has yet to be found (Dyer and Rosenberg 1996).

Other effector molecules

Eosinophils store esterified arachidonic acid in their lipid bodies. Arachidonic acid metabolism through the 5-lipoxygenase pathway results in production and release of LTC_4, which causes vasoconstriction, bronchoconstriction, and smooth muscle contraction (Lewis and Austen 1984). Arachidonic acid metabolism through 15-lipoxygenase results in lipoxins, and metabolism by cyclooxygenase pathways produces prostaglandin E_2 (PGE_2) and thromboxane B_2. Eosinophils also release several oxidative products (including hydrogen peroxide, superoxide anion, and hydroxyl radical and singlet oxygen) and release PAF (Lee et al. 1984).

IMMUNOMODULATORY CAPABILITIES

Although basophils and eosinophils are typically thought of as cells of the innate immune system, they also serve to modify the adaptive immune system by releasing cytokines. In addition, histamine released by basophils has immunomodulatory effects, and eosinophils have the ability to process and present antigen.

Basophils

CYTOKINE RELEASE

Basophils release both IL-4 and IL-13. IL-4 induces $CD4^+$ T-helper (Th) 0 cells to become Th2 cells, and both cytokines can, in combination with ligation of CD40, cause B cells to switch to IgE isotype. Of all PBMCs, basophils are the only ones with the ability to provide IL-4 early in response to a stimulus (Gibbs et al. 2000), releasing preformed IL-4 within 5–10 minutes of IgE stimulation (Gibbs et al. 1996). After activation, basophils also synthesize IL-4 and IL-13 *de novo*, with time-course experiments showing a second peak of IL-4 release after 4 hours and a first peak of IL-13 release at 24 hours (Gibbs et al. 1996).

IL-4 release is increased in basophils exposed to IL-3 but not to basophils exposed to IL-5, GM-CSF, or NGF (Brunner et al. 1993; Dahinden et al. 1997). IL-13 production is also enhanced by IL-3 (Li et al. 1996a). There are probably some differences in the regulation of IL-4 and IL-13 production by basophils, because only IL-13 is secreted from basophils after stimulation with IL-3 alone and IL-4 production is inhibited by the immunosuppressant FK506, whereas IL-13 production is not (Redrup et al. 1998). Also, 20 hours after activation, the amount of IL-4 released from basophils after stimulation with IL-3 and anti-IgE correlates strongly with the percentage of histamine secreted, whereas the amount of IL-13 released does not (Redrup et al. 1998).

Eotaxin also modulates basophil cytokine production, augmenting antigen-dependent IL-4 production and release from basophils by two- to fourfold and lowering the threshold for basophil activation and IL-4 production by 40-fold (Devouassoux et al. 1999). Other factors that enhance basophil IL-4 production include the chemokines MCP-2, MCP-3, MCP-4, RANTES, and eotaxin-2, all of which act on basophils through CCR-3 (Devouassoux et al. 1999), and the recombinant HRF (rp21) (Schroeder et al. 1997).

As they can express CD40 ligand as well as release IL-4 and IL-13, basophils have the ability to induce B cells to switch to IgE isotype (Gauchat et al. 1993), potentially creating a positive feedback loop whereby IgE-dependent activation of basophils results in the production of more IgE by B cells.

ANTIGEN PRESENTATION

Unlike eosinophils, there is no evidence that basophils can act as antigen-presenting cells (APCs).

IMMUNOMODULATORY PROPERTIES OF HISTAMINE

Basophils can modulate the immune response through secreted histamine. Histamine modulates the expression and action of several cytokines, having been shown to increase production of IL-2, IL-5, IL-6, IL-8, IL-10, IL-11, IL-16, GM-CSF, and RANTES and to downregulate production of IL-2, IL-4, IL-12, IFN-γ, and TNF-α (Igaz et al. 2001).

Signaling through the different histamine receptors mediates different effects on the Th response. Triggering of the H1R on $CD4^+$ T cells enhances Th1-type responses, causing increased IFN-γ production and subsequent downregulation of Th2-type responses, whereas triggering through the H2R downregulates both Th1 and Th2 responses (Elenkov et al. 1998; Jutel et al. 2001). As the Th2-type response is integral to the production of IgE through the actions of IL-4 and IL-13, the downregulation of the Th2 arm of the cellular

immune system through H_1- and H_2-receptors may serve as a negative feedback on the response that initially accounted for the production of IgE which led to the basophil degranulation.

It is clear that histamine affects a variety of cell types and modulates the Th1/Th2 balance at several different points. Histamine affects monocytes by decreasing their production of IL-12 (van der Pouw Kraan et al. 1998) and inhibiting ICAM-1 expression induced by IL-18 (Takahashi et al. 2002). Through interaction with the H_2-receptor, histamine causes increased IL-10 and decreased IL-12 production by dendritic cells (Mazzoni et al. 2001). Histamine also increases the release of IL-10 from unstimulated and LPS-stimulated human alveolar macrophages by PGE_2 and nitric oxide (NO) production (Sirois et al. 2000). One study suggests that many of the effects of histamine may be the result of its upregulation of IL-18 production, because addition of anti-IL-18 abolished all cytokine changes caused by histamine in in vitro studies of PBMCs (Kohka et al. 2000).

Eosinophils

CYTOKINE RELEASE

Eosinophils release a multitude of cytokines (see Table 2), many of which amplify a type 2 response. Eosinophils produce and release IL-1α, which can work in concert with APCs as a stimulator for Th2 lymphocytes (Del Pozo et al. 1990; Weller et al. 1993). In murine schistome granulomas, eosinophils are the predominant source of IL-4. Eosinophils also release IL-3, IL-5, and GM-CSF (Kita et al. 1991; Moqbel et al. 1991; Broide et al. 1992; Desreumaux et al. 1993), the cytokines most responsible for eosinophilopoeisis in the bone marrow, suggesting that eosinophil degranulation results in increased eosinophil production. In a murine model of Nippostrongylus infection, eosinophils accumulate at sites of helminth infection and express IL-4 even in mice lacking B and T cells, raising the possibility that eosinophils may even have the capacity to initiate a Th2 response (Shinkai et al. 2002).

In addition to contributing to the Th2 response, several cytokines released by eosinophils play a direct role in the inflammatory response. IL-1α and TNF-α, both secreted by eosinophils (Del Pozo et al. 1990; Weller et al. 1993; Finotto et al. 1994), are potent inflammatory agents that can enhance local blood flow, activate macrophages, and induce fibroblast growth. TGF-α and TGF-β, also released by eosinophils, are potent promoters of fibroblast growth and collagen synthesis and may play a role in the tissue fibrosis that occurs in diseases of chronic eosinophilic inflammation (Todd et al. 1991; Finotto et al. 1994).

It has recently been shown that eosinophils synthesize and release NGF and neurotrophin-3 (Kobayashi et al. 2002), factors that are essential for the survival and development of peripheral neurons. Although the physiological relevance of this finding has yet to be determined, it suggests that eosinophils may be involved in processes such as guiding tissue homeostasis and development. Alternatively, as NGF can activate eosinophils (Solomon et al. 1998), release of NGF by eosinophils may serve as a means by which eosinophil activation is amplified in an autocrine fashion.

ANTIGEN PRESENTATION

Eosinophils express MHC class II (HLA-DR) when cultured with GM-CSF in vitro (Lucey et al. 1989). In vivo, eosinophils taken from sites of inflammation in patients with asthma, allergy, and chronic eosinophilic pneumonia also express MHC class II (Hansel et al. 1991; Beninati et al. 1993). Evidence that eosinophils can function as APCs comes from in vitro and mouse models showing that eosinophils can stimulate antigen-specific T-cell proliferation (Del Pozo et al. 1992; Hansel et al. 1992; Weller et al. 1993). The extent to which eosinophils actually present antigen in vivo is unclear, especially as they are not particularly efficient at phagocytosis, often a first step required for antigen presentation.

BASOPHILIA AND EOSINOPHILIA AS DISEASE MARKERS

Eosinophilia, which is usually defined as an eosinophil count > 500 cells/mm^3, is a common finding in helminth infections, allergy, asthma, and several other diseases. Basophilia is a rare finding in all disease processes except for chronic myelogenous leukemia. Tables 5 and 6 list the infectious and non-infectious diseases in which basophilia and eosinophilia have been reported to occur.

ROLE IN INFECTIOUS DISEASES

The majority of research on eosinophils and basophils has focused on their roles in diseases such as asthma and allergy. In addition to these states, however, it is clear that basophils and eosinophils play large roles in the immunological response to infectious diseases – especially to helminths and possibly to viruses. Despite decades of study, however, the exact function that these cells serve in the response to infection remains unclear.

Helminth infections

BASOPHILS

Several factors suggest that basophils play an important role in the immune response to helminth infections. While a recent retrospective study suggests that basophilia does not occur in helminth infections of humans (Mitre and Nutman 2003), it clearly occurs in animal

models of parasitic infection. One of the earliest reports of this phenomenon came from Chan in the 1960s, who showed that bone marrow and circulating basophil counts increase within 48 hours of subcutaneous injection of Ascaris body (Chan 1965) and ova fluid (Chan 1968) into guinea pigs. Since then, several other investigators have reported similar findings in several different animal models of parasitic infection. *Trichostrongylus colubriformis* infection has been shown to increase basophil numbers in the bone marrow, small intestine, and peripheral circulation of guinea pigs (Rothwell and Love 1975). Infection of rats (Ogilvie et al. 1978; Roth and Levy 1980; Kasugai et al. 1993) and gerbils (Okada et al. 1997) with *Nippostrongylus brasiliensis* resulted in up to a 50-fold increase in peripheral basophil counts at 2 weeks. *Trichinella spiralis* infection in rats (Ogilvie et al. 1980) and guinea pigs (Lindor et al. 1983) also results in a marked basophilia that precedes the onset of eosinophilia by approximately 1 week. Fasciola infection of guinea pigs is associated with a chronic peripheral basophilia that is detectable up to 4 months after infection (Conboy and Stromberg 1991), and strongyloides infection of *Erythrocebus patas* monkeys causes peripheral basophilia that is occasionally detectable for more than a month after infection (Harper et al. 1984).

Basophils clearly respond to helminth infections, because basophils from patients infected with *Toxocara*, *Ascaris*, *Onchocerca*, *Wuchereria*, *Strongyloides*, and *Schistosoma* spp. have been shown to release histamine in response to parasite antigen (Ottesen et al. 1979; Genta et al. 1983; Hofstetter et al. 1983; Nielsen et al. 1994; Gonzalez-Munoz et al. 1999). Helminth infections are associated with high levels of IgE (Rossi et al. 1993; Estambale et al. 1995; Ramirez et al. 1996), and the amount of histamine released by basophils in response to toxocara antigen is proportional to the serum concentration of toxocara antigen-specific IgE (Nielsen et al. 1994).

In addition to high levels of IgE, human helminth infections are also associated with increased production of IL-4, the prototypical Th2 cytokine. Basophils from filaria-infected patients have been shown to release IL-4 in response to infective stage (L3) larvae and filarial antigen (King 2001), and basophils from non-infected individuals have been shown to release IL-4 after stimulation with schistosoma egg antigen (Falcone et al. 1996). Although basophils make up only a small percentage of peripheral white blood cells, they have the ability specifically to recognize many different antigens by virtue of binding different IgE antibodies on their surface. Consequently, it is possible that the number of basophils that specifically recognize and are activated by helminth antigen may equal or even exceed the number of antigen-specific T cells responding to helminths. Indeed, results from a recent study showed that the number of basophils producing IL-4 in response to filarial antigen was usually equal to or greater than the number of IL-4-producing T-cells in filaria-infected patients (Mitre et al. 2004). Whereas filarial antigen was only shown to cause basophil activation in filaria-infected patients with filarial-Ag specific IgE, it has been demonstrated that a glycoprotein from *Schistosoma mansoni* eggs can cause basophils to degranulate and release IL-4 by binding and crosslinking non-antigen-specific IgE (Falcone et al. 1996; Haisch et al. 2001), raising the possibility that some helminth antigens may act as a type of 'super-allergen' by being able to bind directly to the nonvariable portion of IgE. This suggests that, in some cases, basophils may serve as the initial source of IL-4, providing the stimulus for T cells to differentiate toward a Th2 phenotype.

Similarly, homologs of mammalian, translationally controlled tumor protein, a calcium-binding protein that directly stimulates histamine release from basophils, have recently been cloned from *Schistosoma mansoni* (Rao et al. 2002) and the filarial parasites *Wuchereria bancrofti* and *Brugia malayi* (Gnanasekar et al. 2002).

EOSINOPHILS

Eosinophilia is a frequent finding in invasive helminth infections; such eosinophilia is probably mediated by IL-5, because treatment of mice with anti-IL-5 results in ablation of helminth-induced eosinophilia (Coffman et al.

a) Disease in which eosinophilia commonly occurs.

1989; Sher et al. 1990). After treatment of human patients infected with onchocerciasis or lymphatic filariasis, serum IL-5 levels increase and circulating eosinophil levels decrease, suggesting that eosinophils are recruited out of the circulation and into the tissues by IL-5 in response to dying helminths (Limaye et al. 1991, 1993; Cooper et al. 1999). In addition to increased production and recruitment of eosinophils by IL-5, eosinophilia in response to helminth infections may be the result of a prolonged eosinophil lifespan, because eosinophils from splenic granulomas of *Schistosoma mansoni*-infected mice have been shown to be resistant to apoptosis in vivo and protected from Fas–FasL-mediated apoptosis by the absence of Fas ligand expression (Rumbley et al. 2001).

Studies in mice and in vitro clearly show that eosinophils are toxic to helminths. Culture of freshly isolated human eosinophils with antibody-coated *Schistosoma*

mansoni larvae results in death of 14 percent of the parasites. After addition of IL-3, the eosinophils kill over 50 percent of the *S. mansoni* larvae (Rothenberg et al. 1988). IL-5 can also enhance the toxicity of eosinophils against *S. mansoni* (Mazza et al. 1991).

Binding of CD11b and VLA-4 on the eosinophil surface to C3a and plasma fibronectin deposited on the cuticular surface of *Nippostrongylus brasiliesis* larvae after experimental infection of transgenic IL-5 mice allows eosinophils to adhere directly to the larvae (Shin et al. 2001). Electron microscopy reveals that the cuticular surface of *N. brasiliensis* larvae in this model becomes damaged from electron-dense materials released from the eosinophils. Indeed, purifed eosinophil granule proteins have been shown to have direct toxicity on various helminths, including *Trichinella spiralis* (Hamann et al. 1987), *S. mansoni* (Ackerman et al. 1985), *Brugia malayi* (Hamann et al. 1990), and *Trypanosoma cruzi* (Molina et al. 1988). Eosinophil toxicity of helminths has been shown to occur via antibody-dependent (Butterworth et al. 1974) and antibody-independent (Shin et al. 2001) mechanisms.

Whether eosinophils actively protect against helminth infections remains controversial. Several studies using rabbit anti-mouse eosinophil serum, which depletes mice of circulating eosinophils, showed that eosinophils probably have a protective effect against Schistoma, Trichinella, and Trichostrongylus infections (Mahmoud et al. 1975; Grove et al. 1977; Gleich et al. 1979).

In contrast to these findings, more recent studies using anti-IL-5 antibodies to deplete circulating eosinophils in experimental helminth infections have shown mixed results in terms of the importance of eosinophils in mediating helminth protection. Mouse models of Schistosoma, Trichinella, and Trichuris infections found no differences in parasite burden in eosinophil-depleted mice compared with control mice (Sher et al. 1990; Herndon and Kayes 1992; Betts and Else 1999). On the other hand, elimination of eosinophils using IL-5-neutralizing antibodies, although not affecting the number of tissue-migrating larvae recovered from the lungs in primary infection with *Strongyloides venezuelensis*, does result in greater numbers of adult Strongyloides worms in the intestine, suggesting that eosinophils are important in the control of infection, although perhaps not during the initial establishment of infection (Korenaga et al. 1994). Also, anti-IL-5-treated mice become susceptible to re-infection with *Onchocerca lienalis*, a helminth to which mice are usually resistant (Folkard et al. 1996).

Other approaches to ascertain the role of eosinophils in response to helminth infection also come to different conclusions. Mice deficient in IL-5 cannot develop circulating or tissue eosinophilia. These IL-5 KO mice have been shown to have similar susceptibility to *Mesocestoides corti*, *Hymenolepis diminuta*, and *Fasciola hepatica* as control mice (Kopf et al. 1996; Ovington and Behm 1997). *Toxocara canis*, *Strongyloides ratti*, and *Heligmosomoides polygyrias* infections, however, appear to be more severe and cause greater tissue damage in IL-5-deficient mice than in control mice (Ovington and Behm 1997). In one study, IL-5 transgenic mice, which have high baseline peripheral blood eosinophil levels, were shown to have the same susceptibility to infection with *Schistosoma mansoni* as control mice (Freeman et al. 1995). Another study, however, demonstrated that IL-5 transgenic mice have greater resistance against helminths, with a sevenfold decrease in the worm recovery rate 60 days after infection with *Litomosoides sigmodontis* compared with control mice (Martin et al. 2000). In an ex vivo gut loop experimental infection of *Fasciola hepatica*, protection correlated strongly with the frequency of eosinophils in the gut (Van Milligen et al. 1999). CCR3 KO mice, which are unable to recruit eosinophils to the small intestine and skeletal muscle after infection with *Trichinella spiralis*, exhibit normal rejection rates of adult worms from the small intestine but have greater total numbers of cysts in the skeletal muscle and these cysts exhibit less necrosis than those of normal mice (Gurish et al. 2002).

There are several possible explanations for the discrepant results of studies of eosinophils and helminth infections. It may be that eosinophils play different roles in different animal species. Moreover, there are significant differences between human and mouse eosinophils: murine eosinophils lack Fcε receptors (de Andres et al. 1997), and there are large differences between the amino acid sequences of mouse EDN and ECP compared with human EDN and ECP (Larson et al. 1996; Nittoh et al. 1997). Also, eosinophils may be efficacious against some helminth infections (or some stages of the infections) but not all. To date, one of the major barriers to studying the role of eosinophils in helminth infections has been the lack of a specific method for selective depletion of eosinophils. A monoclonal antibody to CCR3 has recently been developed and been shown selectively to deplete eosinophils in mice (Grimaldi et al. 1999). Studies using this antibody are currently under way and will, it is hoped, better elucidate the role of eosinophils in the immune response to helminths.

Viral infections

BASOPHILS

Although the role, if any, that basophils play in host defense against HIV is unknown, it is clear that basophils may be an important reservoir for HIV infection. Basophils express CD4 as well as the HIV co-receptors CCR3 and CXCR4, can be infected with M-tropic HIV in vitro, and have been shown to be infected with HIV in many patients with AIDS (Li et al. 2001). HIV-1 Tat protein upregulates CCR3 expression on basophils, increasing the likelihood that the virus successfully

infects the cells (Marone et al. 2001). IL-16, which can bind to CD4, makes basophils less susceptible to infection with M-tropic HIV (Qi et al. 2002). Notably, HIV-1 gp120 can act as a 'super-allergen' by interacting with the heavy chain variable 3 (V[H]3) region of IgE to induce cytokine and histamine release from FcεR1$^+$ cells (Marone et al. 2001). The physiological significance of this phenomenon is unknown.

Basophils also interact with respiratory viruses. In vitro, infection of human PBMCs with respiratory viruses results in enhanced IgE-mediated histamine release from basophils (Chonmaitree et al. 1988), and experimental infection of allergic rhinitis patients with rhinovirus 16 results in increased plasma histamine levels (Calhoun et al. 1991). Rhinovirus infection of the basophil cell line KU 812 augments anti-IgE-induced histamine release and increases maximal IL-4 and IL-6 production by basophils (Hosoda et al. 2002). These results suggest that some respiratory viruses may trigger asthma attacks by causing release of histamine and type 2 cytokines from basophils. The effect that the basophils have in terms of host defense in these infections is not known.

EOSINOPHILS

Asymptomatic eosinophilia occurs in 18 percent of patients with HIV (Caterino-de-Araujo 1994), and occurrence of eosinophilia in HIV correlates with low CD4$^+$ cell counts (Smith et al. 1994; Tietz et al. 1997). Eosinophilia in HIV patients, however, is neither a useful clinical marker for eosinophil-related diseases nor a predictive factor for the future course of HIV infection. In a study of blood counts in HIV patients over a 4-year period, no etiological agent could be found in patients with eosinophilia (Cohen and Steigbigel 1996). Other than a moderate increase in the prevalence of rash, a case–control study of HIV patients with and without eosinophilia found no significant clinical correlation between eosinophilia and other diseases such as parasitic infection, allergic reaction, or malignancy (Skiest and Keiser 1997).

Like basophils, eosinophils express CD4 and CCR3 and can be infected by macrophage-tropic strains of HIV (Weller et al. 1995; Alkhatib et al. 1997). Eotaxin, which binds to CCR3, diminishes HIV entry into eosinophils (Alkhatib et al. 1997).

Some in vitro data suggest that eosinophils may aid in eliminating HIV. EPO has been shown to have marked antiviral activity against HIV-1 (Klebanoff and Coombs 1996), and eosinophils have been shown to inhibit cellular transduction by a mouse retrovirus through a mechanism dependent on eosinophil ribonucleases (Domachowske and Rosenberg 1997); however, subcutaneous injection of IL-3 into humans with HIV, which resulted in a 17-fold increase in absolute eosinophil counts, caused no significant quantitative changes in viral load, suggesting that IL-3 and corresponding eosinophilia do not enhance HIV elimination in humans (Scadden et al. 1995).

Eosinophils may also play a role in the pathogenesis of respiratory syncytial virus (RSV) infection. Eosinophils are often found in nasal washes of children with RSV (Zhao et al. 2002), and are occasionally found in increased numbers in the peripheral circulation as well (Ehlenfield et al. 2000). Whether eosinophils serve a protective role against RSV has not yet been completely determined, although such a role has been postulated (Rosenberg and Domachowske 2001). The tissue eosinophilia induced by RSV infection may, however, exacerbate asthma. The degree of eosinophilia in nasopharyngeal secretions correlates with the degree of asthma exacerbation in children with asthma who are infected with RSV, but not influenza (Zhao et al. 2002). In addition, higher peripheral blood eosinophil counts at the time of RSV bronchiolitis are associated with an increased risk of developing childhood asthma (Ehlenfield et al. 2000).

DEFINITION AND GENERAL CHARACTERISTICS OF NATURAL KILLER CELLS

Historical perspective

Natural killer cells were discovered in the early 1970s, through their capacity to kill certain tumor cells in cytotoxicity assays in vitro. In the search for evidence of a specific immune response in patients or experimental animals with tumors, several groups observed a cytotoxic activity by lymphocytes isolated from the blood or the spleen. It was soon realized that this activity occurred also in healthy individuals, and had nothing to do with a specific tumor response. Although some considered this activity as 'nonspecific background', others went on to analyze the phenomenon in more detail. This research soon provided evidence that the cytotoxicity was mediated by a previously undescribed, lymphocyte-like cell with unique characteristics, and the term natural killer (NK) cell was then coined (Herberman et al. 1975a, b; Kiessling et al. 1975a, b). Equally important, it became clear that the activity observed in vitro correlated with natural resistance to transplantable tumors in vivo in animals (Kiessling et al. 1975c). The NK cells were soon also identified as the effector cell responsible for a peculiar form of bone marrow transplant rejection that had puzzled immunologists for a decade (Kiessling et al. 1977). The notion of one novel cell type with in vivo relevance triggered further research, mainly in tumor immunology, but eventually also in infection immunology. Evidence for a role of NK cells in the early defense against viral infections soon emerged. Other researchers also observed effects mediated by NK cells in bacterial and parasite infections. The microbiology-oriented NK cell research has been particularly important for defining additional effector functions of NK cells. Their capacity to secrete cytokines such as interferon (IFN)-γ is in many situations more important than the killer function that forms the basis of their name.

It took a relatively long time before NK cell recognition could be defined in molecular terms. Research on inhibitory, major histocompatibility complex (MHC) class I-recognizing receptors, as postulated in the 'missing self' model, provided a platform for identification of the first NK cell receptors (Kärre 1985, 2002; Ljunggren and Kärre 1990). Intensive research during the 1990s has defined a large number of activating and inhibiting receptors (Moretta et al. 1993, 2001; Yokoyama and Plougastel 2003). A challenge for the current and coming years of research is to transform the reductionist study of individual receptors into a comprehensive view of how these molecules interact in decision processes created by different challenges, especially different microbial agents.

Identification and isolation of NK cells – cell surface markers

There is no single cell surface molecule or other feature that can be used to identify all NK cells, and

nothing but NK cells. Any efforts to define or isolate these cells must therefore rely on a combination of characteristics. NK cells are of lymphoid lineage and are often associated with a special morphology, that of the large granular lymphocyte (LGL) (Figure 1) (Timonen and Saksela 1980). In the normal blood of healthy individuals, there is a good correlation between NK cells and this morphological phenotype. However, not all NK cells are LGLs, and not all LGLs are NK cells.

Natural killer cells are usually defined through a combination of cell surface markers – in the human as $CD56^{+}CD16^{+}CD3^{-}$ immunoglobulin (Ig) cells with the morphology of lymphocytes (Moretta et al. 1994; Carson and Caligiuri 1996). CD56 is the neuronal cell adhesion molecule (N-CAM), but it is unclear whether and how this marker relates to the function of NK cells. In the mouse, the allotypic marker NK1.1 is used instead of CD56, although the two markers are completely unrelated (Yokoyama 1999). NK cells express a number of additional adhesion molecules, cytokine receptors, and cognate recognition molecules (Tables 1 and 2), many of which are discussed further later in the chapter in relation to the functional aspects.

The NK cells represent about 5–15 percent of the lymphocytes in the blood, and about 1 percent of the lymphocytes in the spleen. These are the two usual sources for isolation of NK cells in the human and mouse, respectively. An enriched or purified population requires cell sorting by flow cytometry or immunomagnetic beads, based on the combinations of surface marker characteristics discussed above. NK cells can also be isolated from the thymus, liver, and lymph nodes, although they are rare in these tissues.

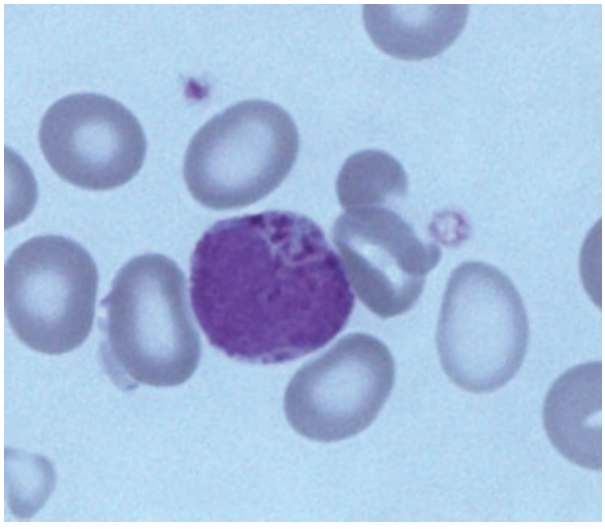

Figure 1 *A large granular lymphocyte. Blood smear – large granular lymphocyte. (Photograph kindly provided by Dr V. Krenn, Charité, Berlin.)*

Table 1 *Cell surface molecules expressed by natural killer (NK) cells*

Antigen	Ligand
CD2	CD58, CD48
CD11a/LFA-1	ICAM-1, ICAM-2
CD11b/Mac1	ICAM-1, ICAM-2, complement
CD16	IgG
CD27	CD70
CD28	B7–1, B7–2
CD40L	CD40
CD44	Hyaluronic acid
CD45/B220	
CD49b/DX5	
CD49e	Collagen, laminin
CD56 (human)	
CD62L	
CD69	–
CD94	
IFN-αβR	IFN-α, IFN-β
IL-2Rβ	IL-2, IL-15
IL-12R	IL-12
IL-18R	IL-18
Asialo-GM1 (rodent)	

ICAM, intercellular adhesion molecule; IFN, interferon; Ig, immunoglobulin; IL, interleukin.

NK cells do not display the typical clonal receptor distribution seen in T and B cells, and they do not rely on rearrangement of gene segments in a germline repertoire for generation of receptors. Hence, their development is not disturbed in severe combined immunodeficient (SCID) or RAG gene-deficient mice (Yokoyama 1999). However, NK cells are heterogeneous in their receptor repertoire, in the sense that different cells express different combinations of activating and inhibitory receptors. In addition, a functional heterogeneity is emerging, at least in the human. The majority of blood NK cells express moderate levels of CD56 in combination with various molecules of the killer cell immunoglobulin receptor (KIR) family (Cooper et al. 2001). This population also expresses high levels of perforin, a pore-forming protein secreted on triggering of the killer machinery. In addition, there is a small subpopulation of blood NK cells that expresses high levels of CD56 in combination with the inhibitory receptor NKG2A, and no receptors of the KIR family. This subset has low perforin levels and seems to be specialized for high cytokine secretion rather than direct killing. The latter subset may be the only NK cells present in the lymph nodes, an organ that was initially thought to be completely devoid of NK cells (Ferlazzo et al. 2004). NK cells are also observed in the capillary beds of the lungs and liver, and they can evidently deliver effector functions in the skin as well as in the peritoneal cavity.

Table 2 *Mouse strains useful for studies of natural killer (NK) cells*

Mutation	Development	Comment
Beige	Normal	Defect in natural killing
Tgϵ26	Compromised	Lack NK and T cells (transgenic for human CD3e
Ly49A#7-tg	Compromised	NK-cell deficiency (accidentally)
IL-15	Compromised	Development and homeostasis
$\gamma c^{-/-}$	Compromised	Reduced cytotoxicity and cytokine production
$Ikaros^{-/-}$	Compromised	Reduced cytotoxicity
$Ets1^{-/-}$	Compromised	Reduce cytotoxicity and cytokine production
$PU.1^{-/-}$	Compromised	Normal cytotoxicity
$IRF1^{-/-}$	Compromised	Reduced cytotoxicity
$ID2^{-/-}$	Compromised	compromised cytotoxicity
$MITF^{-/-}$	Normal	Reduced cytotoxicity and cytokine production
$CEBP\gamma^{-/-}$	Normal	Reduced cytotoxicity and cytokine production
$CD3e^{-/-}$ $Fc\epsilon RIg^{-/-}$	Normal	Compromised specific killing
$Syk^{-/-}$ $ZAP70^{-/-}$	Normal	Compromised specific killing
$DAP12^{-/-}$	Normal	Cytotoxicity and cytokine production compromised
$Fyn^{-/-}$	Normal	Non-MHC receptor-mediated cytotoxicity compromised
$STAT\text{-}1^{-/-}$	Normal	Impaired rejection of tumors
dnSHP1-tg	Normal	Non-MHC receptor-mediated cytotoxicity compromised
$Perforin^{-/-}$	Normal	Perforin-independent cytotoxicity (Fas-L, TRAIL)

γc, common cytokine receptor γ chain; CEBP, CCAAT/enhancer binding protein; Ets1, E26 avian leukemia oncogene 1; Fas-L, Fas ligand; ID2, inhibitor of DNA binding 2; IRF1, interferon regulatory factor 1; MITF, microphthalmia-associated transcription factor; ZAP70, ζ-chain associated protein 70 kDa; DAP12/KARAP, killer cell activating receptor associated protein; STAT, signal transducer and activator of transcription; dnSHP1, dominant-negative SH_2-domain-containing protein tyrosine phosphatase; TRAIL, tumor necrosis factor (TNF)-related, apoptosis-inducing ligand. For further information see (Colucci et al. 2003).

Effector functions

As indicated by their name, the ability to kill various target cells is a central functional feature of NK cells. They possess several different mechanisms to do this, most of which they share with cytotoxic T lymphocytes. The most important one is perforin-dependent killing (Young and Cohn 1986). Perforin is a pore-forming protein, which is stored in the secretory granules of NK cells. When killing is triggered, the secretory apparatus is oriented toward the interface with the target cell, and the granule contents are released in the 'immune synapse' between the two cells (Davis et al. 1999; Henkart 1999; Lieberman 2003). The granules contain additional proteins, such as the serine proteases granzyme A, B, and C. These are introduced into the target cell via the pores formed by perforin, and subsequently activate apoptotic pathways. These, as well as osmotic effects created by the perforin-induced pores, eventually lead to target cell death. The process involves considerable temporospatial specificity – one NK cell can bind and initiate a 'synapse' with several cells simultaneously, and still kills only those that present the appropriate triggering signals; the others are left intact (Eriksson et al. 1999).

This rapid and efficient killer mechanism, allowing elimination of numerous target cells within minutes to hours, is defective in perforin-deficient mice. The NK cells from such mice can still kill many target cells, although this usually requires longer observation times (12–24 h) (Wallin et al. 2003). This killing is dependent on membrane-bound death receptors such as Fas ligand (Fas-L or CD178) and tumor necrosis factor (TNF)-related, apoptosis-inducing ligand-dependent receptors (Arase et al. 1995; Kayagaki et al. 1999). These interact in a cognate fashion with Fas and tumor necrosis factor-related, apoptosis-inducing ligand (TRAIL) and can thereby activate apoptosis in target cells expressing these molecules. Such mechanisms may dominate in certain situations, even when the NK cells express perforin.

Natural killer cells can also secrete cytokines, particularly IFN-γ and TNF-α (Trinchieri et al. 1984; Degliantoni et al. 1985). These cytokines may be directly cytotoxic in certain situations, but they are mainly viewed as regulators of other cellular functions. In this way NK cells may contribute to host defense by influencing infected cells and other white blood cells as well as noninfected cells outside the immune system, but which nevertheless are important for the inflammatory response (e.g. endothelial cells) (Trinchieri 1995; Biron et al. 1999). For example, IFN-γ induces increased expression of a number of cell surface molecules, including MHC class I and II products and intracellular proteins involved in antigen processing. IFN-γ can also induce intracellular pathways that limit the replication or even lead to the direct elimination of microorganisms. It can influence the profile of the ensuing specific

adaptive response, deviating the T cells toward a T-helper (Th) type 1 response. Other cytokines that can be secreted by NK cells include the interleukin (IL)-10, IL-13, and granulocyte–macrophage colony-stimulating factor (GM-CSF).

The soluble effectors expressed by NK cells also include molecules with antimicrobial activity. The peptide granulysin is one of the granule components, allowing NK cells to exert direct bactericidal effects (Krensky 2000). Finally, a relatively recently discovered effector function involves cognate receptors that can stimulate T cells directly. The cell surface molecule 2B4 and its ligand CD48 appear to play a central role here (Lee et al. 2003).

Many stimuli can induce several parallel effector functions, e.g. the recognition of target cells via activating and inhibitory receptors will in many cases lead to cytotoxicity as well as IFN-γ secretion. Other stimuli, such as cytokine receptors, may elicit more restricted action.

Methods to study NK cell function in vitro and in vivo

Natural killer cell activity is often measured with the type of cytotoxicity assays that allowed their discovery (Kiessling et al. 1975a, b; Herberman et al. 1975a, b). These are usually based on assessing the proportion of target cells that releases an intracellular marker as a sign of cell damage or death after incubation with a cellular preparation containing NK cells. The target cells are usually 'labeled' with the marker before the assay, e.g. with the isotope ^{51}Cr that binds to intracellular proteins and is therefore minimally released during 4–8 h used for the assay, unless the target cells are killed.

Some target cells, e.g. normal resting cells, label poorly or are difficult to prepare to give minimal 'spontaneous release' of the isotope in the absence of killer cells. An alternative in such cases in experimental animal research is a type of assay based on 'in vivo elimination'. Target cells labeled with isotope or fluorescent dyes are inoculated into mice, usually intravenously, and the numbers of surviving cells are measured by sacrificing the animals and counting radioactivity or fluorescent cells in different organs (Riccardi et al. 1979). These assays have the advantage of demonstrating killer activity directly in vivo, which is usually more efficient than the in vitro activity. When used with tumor cells, the most efficient NK cell-mediated elimination is usually observed in the lungs, where many tumor cells are initially trapped in the capillary bed (Smyth et al. 2002). This type of assay has so far been used only to a limited extent in microbiological NK research.

A more complex, but of course highly relevant, way to study NK cells is to assess their influence on the incidence or outcome of disease or a treatment. This has been done extensively in relation to infectious agents as well as tumors. In such studies, it is of course vital to have parallel control animals in which NK cells are defective in some way or totally depleted. Measuring the survival or replication of the microorganism, and/or signs of disease and ultimately death of the infected animal, can then follow infection. Some examples on the role of NK cells in infections are discussed further below. In cancer research, the outcome can be measured by complete rejection or outgrowth of a subcutaneously inoculated tumor (Kiessling et al. 1975c). This requires the use of titrated, low doses of tumor inocula, but gives the advantage of demonstrating that NK cells can 'finish the job' and eradicate the last tumor cells (Kärre et al. 1986). Alternately, higher tumor doses can be used, and the outcome assessed by measuring the tumor size or number of metastases at given time points. NK cells are particularly efficient at preventing hematogenous metastases to the lungs (Smyth et al. 2002), which may reflect their efficient activity in the blood and the capillary beds. NK cells have been studied extensively in experimental bone marrow transplantation in lethally irradiated mice (Kiessling et al. 1977; Bennett et al. 1995; Barao and Murphy 2003). The outcome is then evaluated about a week after the transplantation, and based on assessing the spleen colonization by transplanted cells. This is done either by counting colonies or by measuring how an injected isotope is taken up specifically by proliferating hematopoietic cells.

Controls used to assure that effects are caused by NK cells are usually based on removal of the NK cells from the cell population or the animal. In this case, most investigators use treatment with a monoclonal antibody or antiserum directed against a cell surface marker of NK cells, such as DX5, NK1.1, or asialo GM1 (Ehl et al. 1996). As these reagents are not entirely specific for NK cells, additional controls may be required, e.g. NK 1.1 is expressed on a subpopulation of T cells, the so-called NK-T cells, and it may therefore be appropriate to perform the experiment also in mice lacking such cells. There is, to date, no natural mutant or intentionally constructed gene knock-out mouse with a complete and selective lack of NK cells. However, an experiment aimed at producing a transgenic strain unexpectedly led to a complete NK cell defect in one founder, presumably as a result of the insertion site of the transgene (Kim et al. 2000). The strain derived from this founder is a useful tool to study development of NK cells, but can also be used as a negative control for NK cell effects in vivo, particularly in long-term experiments where it is difficult to maintain absence of NK activity by repeated injections of antibodies (Table 3). Several genetically manipulated mouse strains with an approximately normal size of the NK cell population, but with defects in single receptors or signal transduction pathways affecting NK cell functions, have been established (Colucci et al. 2003). These strains will be useful to dissect the importance of different NK functions in

Further inhibiting receptors: P75/AIRM, IRp60, LAIR-1, gp49B1.
CHO, Chinese hamster ovary; CMV, human cytomegalovirus; HA, hemagglutinin; iDCs, immature dendritic cells; ITIM, immunoreceptor tyrosine-based inhibitory motif; KIR, killer cell immunoglobulin-like receptors; MCMV, murine cytomegalovirus; n.d., not defined yet.
Low-affinity ligands are indicated in parenthesis.
a) HLA-C: group 1 – Ser-77, Asn-80 in Cw1, Cw3, Cw7, Cw8; group 2 – Asn-77, Lys-80 in Cw2, Cw4, Cw5, Cw6.
b) As 'activating' have been designated Ly49 receptors (1) for which stimulatory activity has been revealed or (2) that have no ITIMs and a positively charged residue in the transmembrane segment (Anderson et al. 2001; Kane et al. 2001).

complex in vivo scenarios, e.g. in infectious diseases. Similarly, mice defective in genes critical for various effector functions can be used to study exactly how NK cells contribute to a complex response or development of disease.

There are mice with a profound immune deficiency that involves NK cells as well as other cells, e.g. mice deficient for the common γ chain of cytokine receptors (γc) (Table 3). Despite such a broad defect, these mice can be used for the study of NK cells by adoptive transfer of isolated NK cells. Cytokine-stimulated NK cells can also be used in adoptive transfer to improve the resistance to tumor cells in normal mice.

Ontogeny and regulation

Like other white blood cells, NK cells are derived from hematopoietic stem cells in the bone marrow. In the fetus, NK cells and other lineages also develop in the yolk sac, liver, and aorta–gonad–mesonephros region. Studies in mice indicate that generation of NK cells may be critically dependent on the microenvironment of the bone marrow during adult life. Mice treated with the marrow-ablating agents ^{89}Sr and estradiol, in which other pathways of myelo- and lymphopoiesis are taken over by the spleen, show severely impaired NK cell development (Colucci et al. 2003). Stroma cells of the marrow appear to have a critical role, providing cytokines as well as cognate interactions required for NK cell development.

Through the use of well-defined culture conditions, it is possible to generate NK cells from hematopoietic cells from different sources in the mouse as well as in the human (Mrozek et al. 1996; Williams et al. 1997; Colucci et al. 2003). Multiple intermediate stages have been proposed. Although these differ between species, source of stem cells, and culture conditions, a general pathway emerges that is remarkably similar in the human and the mouse. This simplified scheme has three phases.

The first phase leads to NK cell precursors, via initial commitment to the lymphoid lineage and subsequently to the NK cell lineage. The NK precursors in the human as well as in the mouse express the IL-2 receptor IL-2Rβ, but lack many of the typical NK cell markers. The second phase leads to immature NK cells, during which the NK precursors gradually acquire surface markers and several functions of NK cells. NKRP-1 and CD2 molecules appear early, followed by DX5 (mouse) or CD56 (human), in parallel with the development of the cytolytic potential. The MHC receptors are acquired late; those of the NKG2 family precede those of the Ly49 (mouse) and KIR (human) families. In the third and final phase NK cells are exported to the periphery. Phase 1 and at least part of phase 2 can be achieved in culture by the correct cytokine combinations, without the need for stromal cells. The cytokines stem cell factor (SCF) (also known as c-KIT ligand), fetal liver kinase 2 (FLK2) ligand (also known as FMS-like tyrosine kinase 3 ligand or FLT3L), and IL-7 can drive the cells through phase 1, although none of these is essential by itself for NK development in vivo (Williams et al. 1997). IL-15 is critical in phase 2 (Mrozek et al. 1996). The latter requirement may explain the block in NK cell development in mice with common cytokine receptor γ-chain deficiency – this chain is an essential part of the IL-15 and IL-2 receptor. Although high doses of IL-2 can substitute for IL-15 in vitro, there is overwhelming evidence that in vivo development is critically dependent on IL-15, and not at all on IL-2. Under the influence of IL-15 in vitro, NK cells acquire cytotoxic capacity, but they still lack several characteristics of mature NK cells, such as receptors of the Ly49 or KIR families. Complete maturation requires interaction of NK cell precursors with MHC and possibly other molecules on bone marrow stromal cells, in order to develop and fine-tune the receptor repertoire (Roth et al. 2000; Raulet et al. 2001). The latter aspect is discussed separately.

Developmental processes are regulated by transcription factors, some of which can act as crucial master switches in hematopoietic lineage commitment (Colucci et al. 2003). Mice deficient in the Ikaros gene show a block in lymphoid development, including T, B, and NK cells, whereas myelopoiesis is unaffected (see Table 3). NOTCH-1 and PAX5 act as master switches for the development of T cells and B cells, respectively. Mutations in these genes do not affect NK cell development. There is evidence that ID molecules (inhibitors of DNA-binding proteins), which negatively regulate the basic-loop-helix (bHLH) family of DNA-binding proteins, are important to favor the NK over the T- and B-cell lineage (Yokota et al. 1999). Deficiency in several other transcription factors can partially impair NK cell development, or skew the receptor repertoire (Colucci et al. 2003).

Natural killer cell precursors can be isolated from the thymus. It is, however, not clear whether this signifies a closer relationship to the T-cell lineage. In any case, the thymus plays no critical role in NK cell development; athymic patients (di George syndrome) and mice (nu/nu genotype) have normal if not increased NK cell numbers and activity (Yokoyama 1999).

Once mature, NK cells have a lifespan of at least several weeks. They circulate in the blood and can enter mucosae as well as parenchymatous organs. A special subset is detected in the placenta (Moffett-King 2002). During local infection or inflammation, NK cells may infiltrate the site by attraction through chemokines and the use of integrins such as very late antigen 4 (VLA-4) (or CD49d/CD29) (see Table 1). The homeostatic survival may, like NK development, depend critically on IL-15. Adoptive transfer experiments suggest that mature NK cells are blocked from dividing under normal conditions, but homeostatic proliferation can

take place if the number of NK cells is low (Prlic et al. 2003). There is a vast proliferation on overproduction of the cytokine IL-15 in vivo and NK cells may become dominant in the spleen (Fehniger and Caligiuri 2001). In vitro, NK cells can be induced to proliferate by IL-2. As a result of the constitutive expression of IL-2Rβ, they are the major responding cell population when normal blood or spleen cells are exposed to high doses of IL-2, in what has been termed lymphokine-activated killer (LAK) cultures (Rosenberg 1988; Yokoyama 1999). Hence, they are the major effector cells in the anti-tumoral responses observed after adoptive transfer of LAK cells in experimental and clinical situations (Smyth et al. 2002). The physiological role of IL-2 in NK cell regulation and proliferation is unclear, but it is not a critical factor for development or proliferation of NK cells in vivo (Colucci et al. 2003). There is evidence for nonspecific, cytokine-driven, as well as specific, cognate, recognition-driven proliferation of NK cells during viral infection (Biron et al. 1999).

Many cytokines, chemokines and other mediators can increase the cytotoxic activity of NK cells. Type I IFNs secreted in response to virus infection or artificial stimuli, such as poly(I:C) and tilorone, are frequently used to optimize NK activity in murine experimental models (Biron et al. 1999; Yokoyama 1999). IL-12, IL-18, IL-21, as well as several chemokines can all act to increase NK cytotoxic function (Trinchieri 2003b). Combinations of one or more of these factors often show potentiating effects. Some pathways of regulation have a more profound influence on certain NK cell functions. There is, for example, dichotomy in murine cytomegalovirus (CMV) infection where IL-12 appears more important for NK cell-derived IFN-γ, whereas type I IFNs induce the cytotoxic function. NK cytotoxicity can be down-regulated by IL-10 and transforming growth factor β (TGF-β) (Biron et al. 2002).

Various conditions, diseases, diets, and activities – from high yogurt consumption to laughter and space trips – have been investigated with respect to their influence on NK activity. It is difficult to discern any specific patterns or regulatory pathways from the literature. In general, NK activity may vary considerably and appears relatively easy to modulate on a short-term basis. The functional impact of such spontaneous or induced alterations is unclear.

SPECIFICITY OF NK CELLS – A BALANCE BETWEEN ACTIVATING AND INHIBITORY RECEPTORS

The 'missing self' model

It is now clear that the specificity of NK cells depend on the integration of different recognition events mediated by activating as well as inhibitory receptors. This basic paradigm was first formulated within the 'missing self' model for NK cell recognition (Figure 2) (Karre 1985, 1997, 2002; Ljunggren and Kärre 1990). Briefly, this model proposed that one (but not the only) function of NK cells is to recognize and act on information that is missing in the target and present in the host rather than the opposite, which is how T cells work. More specifically, the information in question would be host MHC class I molecules. An immune mechanism eliminating cells without, or with too few, MHC class I molecules could have evolved as an alternative, as well as a necessary complement to T cells: an alternative because aberrant cells do not always express novel epitopes – loss of gene products might represent an early or even unique change in infected or transformed cells; complementary, because without MHC class I molecules, no antigens would be presented to CD8 T cells, which open for microbial escape mechanisms targeting this pathway. The postulated recognition strategy would also eliminate cells from other individuals, as a result of lack of host MHC molecules. Exposure to such cells occurs frequently in certain invertebrates, for which it has long been recognized that they possess graft rejection mechanisms based on self-recognition (Kärre 2002). Transfer of cells between individuals can also occur in

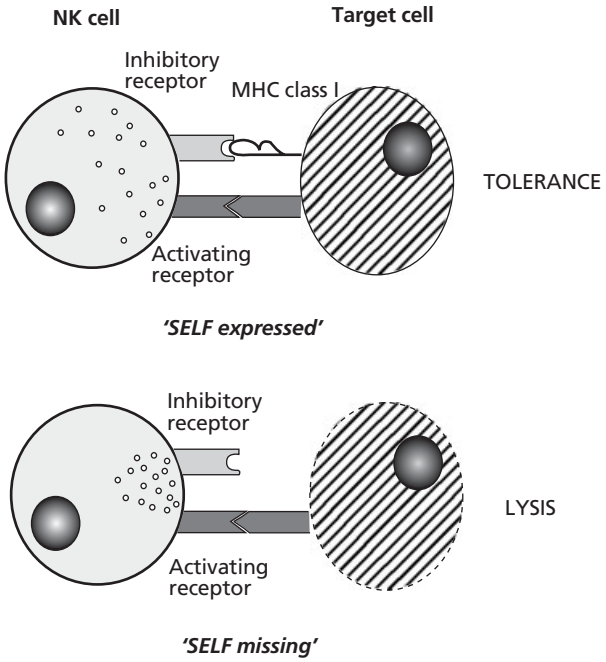

Figure 2 *The 'missing self' model. The expression of major histocompatibility complex class I (MHC class I) (*SELF expressed*) on a potential target cell can be sensed by inhibitory natural killer (NK) cell receptors. Tolerance is caused by dominance of inhibitory signals over NK cell triggering signals exerted by activating receptors engaging ligands on the potential target cell. Reduced or no MHCI expression (*SELF missing*) leads to a reduced or lack of inhibitory signals. Consequently activating signals dominate and killing of the target cell is triggered (Kärre 1985; Ljunggren and Kärre 1990).*

mammals, e.g. during intimate contacts or pregnancy, and this could represent a way for spreading infections. It can thus be argued that mechanisms in 'primitive' defense systems may have evolved further and adapted to the MHC system of mammals in the form of missing self-recognition.

This model provided a number of testable predictions (Kärre 2002), many of which are alluded to in the sections on cancer and transplantation in this chapter. A key prediction related to the main mechanistic model for missing self-recognition, depicted in Figure 2, is based on the idea that NK cells depend on two (sets of) receptors, one activating and one inhibiting. The activating receptor(s) were postulated to recognize ubiquitously expressed ligands, present on most normal cells. This would allow NK cells to bind most cells in the body and receive a preliminary triggering signal. The ultimate decision would then be taken by the inhibitory receptors, recognizing one or more self MHC class I ligands of the host. This would inhibit the triggering signal. If critical class I molecules were missing or too few in number, the inhibitory signal would be insufficient, and lysis of the target cell would proceed by default. This predicted the existence of MHC class I allele-specific receptors on NK cells, and that antibodies prepared against such receptors should induce lysis (by blocking of the inhibitory recognition) rather than block it. This experimental prediction was confirmed with the identification of two different inhibitory receptor families in the human and mouse, respectively (Karlhofer et al. 1992; Moretta et al. 1993, 1994; Yokoyama 1999). The use of antibodies against such receptors allowed a further dissection of specificity and eventually the identification of activating receptors. Although the basic platform provided by the missing self model has turned out to be correct, it is now clear that the picture is immensely more complex, with a variety of activating and inhibitory receptors balancing each other. The decision does not always lie with the inhibitory receptors – some of the activating receptors recognize ligands expressed only by infected or stressed cells, and they can induce NK effector functions even if the target cell expresses self MHC class I molecules (Moretta et al. 2001; Raulet 2003; Yokoyama and Plougastel 2003). Most of the known NK receptors are summarized in Table 4; the most important ones are discussed in more detail below.

Inhibitory receptors

Natural killer cells express inhibitory receptors that recognize MHC class I molecules with varying degrees of allele specificity. Interestingly, these receptors are encoded by two entirely different gene families in the human and in the mouse – the KIR and the Ly49 receptors (Ly49R) in the lectin-like superfamily, respectively (Moretta et al. 2001; Yokoyama and Plougastel 2003). Even though the proteins are in two different structural groups, the receptor systems in the two species show remarkable similarities at the functional level. Both types of receptor recognize a subgroup of MHC class I alleles. Both deliver inhibitory signals by immunotyrosine inhibitory motifs (ITIM) (with the sequence V/I–x–Y–x–x–L/V) in the cytoplasmic tail, which on phosphorylation can recruit phosphatases acting on substrates in the signaling pathways initiated by activating receptors (Lanier 2003). Both are encoded in complex gene families showing considerable polymorphism between individuals, and also include activating receptors of similar specificity and structure, except for the ITIM in the cytoplasmic tail (Trowsdale et al. 2001; Yokoyama and Plougastel 2003).

Table 4 *Key features of signal transduction in natural killer (NK) cells*

Receptor	Module/adaptor	Downstream elements
$Ly49_{inhibiting}$	ITIM	SHP1
$Ly49_{activating}$	+TM/DAP12	SYK, ZAP70
$KIR_{inhibiting}$	ITIM	SHP1
$KIR_{activating}$	+TM/DAP12	SYK, ZAP70 – PLCγ1, ERK1/2
CD94/NKG2A	ITIM	SHP1
CD94/NKG2C, -E	+TM/DAP12	SYK, ZAP70
NKG2D	$+TM/DAP10_{(YINM)}$[a], $+TM/DAP12_{(ITAM)}$[b]	SLP-76, PI3K, Grb2 – Vav, PLCγ2, SYK, ZAP70
2B4	SAP or SHP1; LAT	PI3K
NKp30	FcεRIγ, CD3ζ	SYK, ZAP70
NKp44	+TM/DAP12	SYK, ZAP70
NKp46	FcεRIγ, CD3ζ	SYK, ZAP70
Nkrp-1c	FcεRIγ, CD3ζ	SYK, ZAP70
CD16	FcεRIγ, CD3ζ	SYK, ZAP70 – PI3K, PLCγ2, Vav

ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; KIR, killer cell immunoglobulin receptor; LAT, linker for activation of T cells; PI3K, phosphatidylinositol 3-kinase; PLCγ1, phospholipase C γ1, SAP, SLAM-associated protein; SHP1, SH_2-domain-containing protein tyrosine phosphatase; +TM, positively charged residues in the transmembrane portion; ZAP70 – ζ chain-associated protein 70 kDa. More detailed information is provided in Colucci et al. (2002), Lanier (2003), and Trinchieri (2003a).

a) Resting and activated NK cells.

b) Activated NK cells.

Both types of receptor are expressed in complex patterns within one individual, yielding NK cells or clones or subpopulations with different but partly overlapping combinations of receptors (Raulet et al. 2001; Parham and McQueen 2003). Most importantly, both types of receptor allow the NK cells to distinguish between cells with normal or insufficient self MHC class I expression, by inhibiting effector function in response to the former but not to the latter. In the following, the mouse and human receptors are discussed separately, with emphasis on the features that distinguish them. It is nevertheless clear that the unifying functional aspects dominate. It is a conundrum why evolution has selected two different complex receptor systems with such similar functions in different species.

HLA CLASS I RECOGNIZING KIR RECEPTORS

As evident from their name, the KIR belong to the immunoglobulin superfamily of genes. The KIR genes are located within a larger gene complex termed the leukocyte receptor cluster (LRC) on chromosome 19q13.4 (Trowsdale et al. 2001). Fourteen different expressed KIRs have been described so far (Lanier 1998; Parham and McQueen 2003). The inhibitory receptors have two or three Ig-like folds, and the commonly used terminology is partly based on this feature (e.g. KIR2DL1 means KIR of 2 Ig-like domains, with long cytoplasmic tail including ITIM). As summarized in Table 2, the 2D KIRs distinguish two major subgroups of HLA-C alleles on the basis of a dimorphism involving residues 77 and 80. The KIRs bind on top of the MHC class I molecule, interacting with both α helices and the peptide (Boyington and Sun 2002; Natarajan et al. 2002) (Figure 3). This explains why the peptide bound by the MHC molecule can influence the KIR recognition, although there is no generalized difference between self and nonself (e.g. microbe-derived) peptides. The KIR3DL1 receptor recognizes a subgroup of HLA-B molecules with the Bw4 serological motif determined by residues 77–83, in a manner that can also be influenced by the bound peptide.

A given NK clone can express between 0 and 3 inhibitory KIRs. This expression pattern appears stable within each clone (Lanier 1998). The composition and expression pattern of the KIR-gene complex differ among individuals (Vilches and Parham 2002). The expression pattern is genetically determined; it is stable within one individual and similar in monozygotic twins but, surprisingly, it is not strongly influenced by the HLA type of the individual. The issue of receptor repertoires in rela-

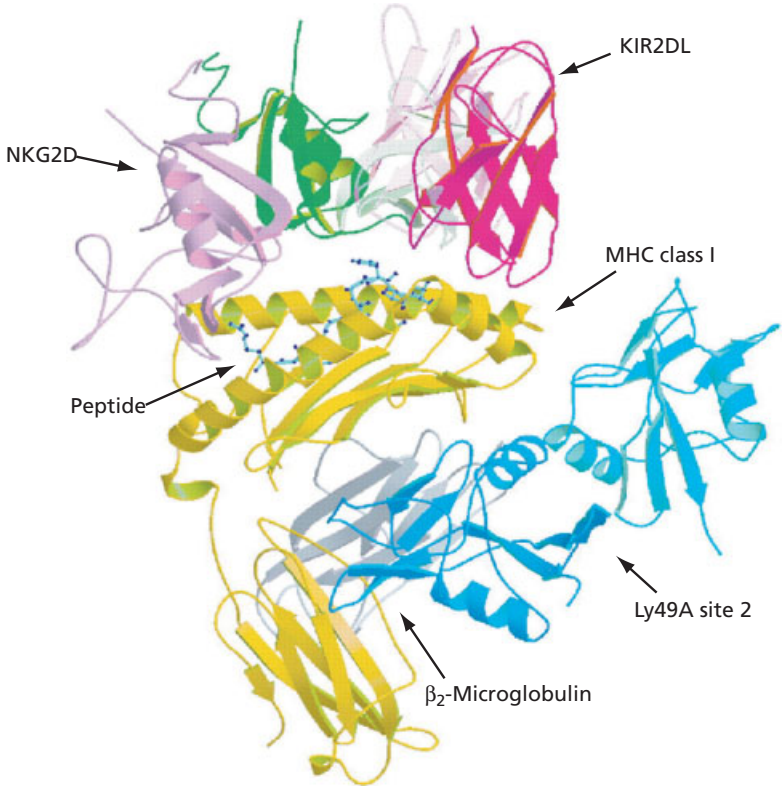

Figure 3 *Structural aspects of major histocompatibility complex class I (MHC class I) recognition by three natural killer (NK) receptors. Binding sites for Ly49A, KIR2DL, and NKG2D on MHC class I (shown is H-2DS^d). Ly49A interacting at site 2 is depicted in cyan/light blue, KIR2DL in magenta, and NKG2D in green/pink. (Figure reproduced with permission from Natarajan et al. (2002) © 2004 Annual Reviews. For detailed discussions see Boyington and Sun (2002); Natarajan et al. (2002), and Dam et al. (2003).)*

tion to tolerance and disease susceptibility is discussed in more detail below.

In addition, the LRC contains the *LIR/ILT* gene family, which includes inhibiting as well as activating receptors (Borges and Cosman 2000; Colonna et al. 2000; Trowsdale et al. 2001). They differ from KIRs in the expression pattern, and are found mainly on other cells in the immune system (Natarajan et al. 2002), e.g. LIR-1/ILT-2 is expressed by B cells, macrophages, and dendritic cells, and only on a smaller fraction of NK cells. This receptor can recognize several different MHC class I molecules but, interestingly, its affinity for the human cytomegalovirus (HCMV) protein UL 18 is 1000-fold higher (Chapman et al. 1999). LIR-2/ILT-4 also bind to MHC class I molecules, whereas the specificity of other members of this family is elusive.

H-2 CLASS I RECOGNIZING LY49 RECEPTORS

The *Ly49* genes are encoded within the NK gene complex (NKC) of distal chromosome 6 in the mouse, together with several other genes that also belong to the lectin superfamily (Yokoyama and Plougastel 2003). There are, however, structural features of Ly49 molecules that argue against a true lectin function, i.e. carbohydrate recognition. A total of 16 full-length Ly49 genes have been identified; the number of genes varies between different mouse strains (Kane et al. 2001). They are expressed as homodimers with type II membrane orientation on the cell surface (Lanier 1998). Like the KIR family, the Ly49 family also includes genes that encode activating receptors.

The Ly49 receptors bind mouse MHC class I molecules with varying degree of allele specificity (see Table 4) (Kane et al. 2001). The Ly49A receptor, co-crystallized with its ligand, surprisingly revealed two sites of interaction: 'site 1' at the top of the groove near the N terminus of the peptide, and 'site 2' below the antigen-binding groove, with several contact residues in the $\alpha 3$ domain and β_2-microglobulin (Kane et al. 2001; Natarajan et al. 2002). Although 'site 1' was initially believed to represent the physiological binding, multiple lines of evidence now argue in favor of 'site 2' being the important recognition zone (Dam et al. 2003). This puts the issue of allelic specificity in focus, because many contact residues at 'site 2' are nonpolymorphic. The most likely explanation is that alterations in polymorphic residues distant from the contact zone can nevertheless affect it by structural changes transmitted through the molecule, ultimately affecting the orientation of nonpolymorphic contact residues. Even polymorphic residues in the floor of the antigen-binding groove can influence allele specificity, which may explain why certain Ly49 receptors are influenced by the nature of the peptide bound to the groove. Perhaps the opposing ways by which KIR and Ly49 molecules bind and distinguish different MHC class I molecules may explain why the two species have evolved different types of receptors.

Each NK cell expresses between 0 and 6 Ly49 receptors, the average estimated as being 2.6 different ones per cell (Kubota et al. 1999; Raulet et al. 2001). The development of the inhibitory receptor repertoire is discussed below.

HLA-E/QA-1 RECOGNIZING NKG2A RECEPTORS

NKG2A receptors are also encoded in the NKC, but, in contrast to the Ly49 family, they and the family of genes they belong to are encoded in the syntenic human chromosome 12p13 (Yokoyama and Plougastel 2003). NKG2A, with two intracytoplasmic ITIMs, is expressed as a heterodimer together with CD94, also encoded within the NKC (Carretero et al. 1997; Lanier 1998). NKG2A recognizes the nonclassic conserved MHC class I molecule HLA-E or its homolog Qa-1 in the mouse. These ligands are not transported from the endoplasmic reticulum (ER) to the cell surface unless they bind peptides with specific anchor motifs, present mainly in leader sequences of polymorphic MHC class I molecules (Braud et al. 1998). Paradoxically, the loading of such leader sequences in HLA-E/Qa-1 molecules requires the ER membrane-bound peptide transporter associated with antigen presentation (TAP). The NKG2A receptor will thus allow the scanning for expression of MHC class I molecules and/or TAP on potential target cells. Reduced production of such molecules will indirectly lead to insufficient HLA-E/Qa-1 expression, which is required to inhibit via the NKG2A receptor (Leibson 1998).

The division of labor between NKG2A and KIR/Ly49 receptors is not clear. Perhaps they are used as complementary tools to sense intact antigen-processing/MHC class I machinery. NKG2A can be expressed together with one or several KIRs, but they can also be expressed in the absence of KIR.

INHIBITING RECEPTORS WITH OTHER SPECIFICITIES

The inhibiting receptors in the mouse also include NKR-P1B and -D. The latter recognizes a lectin expressed by dendritic cells. Interestingly, the gene for this inhibitory ligand is closely linked to the receptor, suggesting that tolerance in this system evolved by linked inheritance of receptor and ligand (Iizuka et al. 2003). In the human, an Ig-like molecule termed p75/AIRM has been identified as an ITIM containing inhibitory NK receptors. It is a member of the sialoadhesin family in the LRC, and it is also expressed by myeloid cells. It mediates sialic acid-dependent recognition but the functional specificity is unknown (Vitale et al. 2001).

The existence of inhibitory receptors with specificities other than MHC class I suggests that the 'missing self' concept may be extended to include situations where target cells need to be protected from NK cells, although MHC class I expression is suboptimal. One

obvious example is the red blood cell. It is not known how erythrocytes escape NK lysis. So far, unknown inhibitory receptor–ligand pairs represent one possibility, but it is also possible that red blood cells do not express adhesion molecules and activating ligands for initial binding and triggering of NK cells.

Activating receptors

ACTIVATING RECEPTORS IN THE KIR AND LIR FAMILIES

Several of the inhibitory KIRs have closely related homologs, which, however, differ in that they only have a short cytoplasmic tail, without ITIMs. These receptors are designated with an S (for short cytoplasmic tail) instead of a D, e.g. KIR2DS1. They possess a charged amino acid in the intramembrane-spanning domain (Lanier 1998), allowing the association with the adaptor molecule KARAP/DAP-12 that couples to activating signal transduction pathways through immunoreceptor tyrosine-based activation motifs (ITAM) in their cytoplasmic tail (Tomasello et al. 2000; Lanier 2003). These are based on the semiconserved peptide sequence YxxL(I)$x_{6–8}$YxxL(I) (Lanier and Bakker 2000). Cross-linking of the activating KIRs thus leads to triggering of NK cells, although the role for this type of recognition for overall NK cell function is not clear. It could represent one of several activating recognition systems for ligands expressed by most cells, and necessary for NK cells to mediate surveillance for the missing self. A more popular idea is that the activating KIRs directly recognize ligands preferentially expressed by infected or stressed cells – either 'altered self' in the form of MHC class I/peptide combinations, or pathogen-encoded, MHC class I-like molecules. There is evidence that activating KIRs may have lower affinity for MHC class I ligands than inhibitory KIRs, and that they are mostly expressed together with the inhibitory homolog (Khakoo and Brooks 2003). These aspects could be important to avoid autoreactivity. As discussed below, the activating KIRs appear to undergo rapid evolution, in line with the idea of an evolutionary pressure created by pathogens.

Some receptors in the LIR/ILT family, such as LIR-6a/b and LIR7/ILT1, share the features of activating KIRs, i.e. a short cytoplasmic tail with a charged amino acid in the membrane-spanning region (Borges and Cosman 2000; Colonna et al. 2000). The function of activating LIRs is not known.

ACTIVATING RECEPTORS IN THE LY49 FAMILY

The Ly49 family also includes activating receptors. Ly49H and Ly49D are the most well characterized (Nakamura et al. 1999; Yokoyama and Plougastel 2003). Like the activating KIRs, they lack ITIMs (despite a long cytoplasmic tail) and instead harbor a charged amino acid in the membrane-spanning region. Similar to activating KIRs, this allows them to signal through the adaptor molecule KARAP/DAP-12 (Lanier and Bakker 2000). Ly49H recognizes a murine cytomegalovirus (MCMV)-encoded ligand, and this receptor is indeed the product of a CMV resistance gene studied for a long time in the mouse strain C57BL, as discussed below (Scalzo et al. 2003). Ly49D, also associating with DAP-12, can bind to the murine MHC class I molecule H-$2D^d$. Ly49D$^+$ NK cells from mice lacking H-$2D^d$ can use the receptor to kill cells that express this MHC allele (Nakamura et al. 1999). An appealing hypothesis that integrates these seemingly disparate specificities of Ly49H and Ly49D, addressing the function and evolution of activating of MHC class I-recognizing receptors in general, is discussed below.

NKG2D: AN ACTIVATING RECEPTOR RECOGNIZING LIGANDS INDUCED IN STRESSED, INFECTED, AND TRANSFORMED CELLS

NKG2D is closely linked genetically to NKG2A and -C, but only distantly related to them with respect to sequence homology (28 percent). Furthermore, it is expressed as a homodimer rather than complexing with CD94. It is expressed by T cells (all in the human and by subsets of γδT and activated αβT cells in the mouse) and by activated macrophages (Raulet 2003). Through a charged amino acid in the membrane-spanning region, it can associate and induce activating signals through the adaptor molecule DAP10 in T cells, which enables it to work as a co-receptor for T-cell receptor (TCR) triggering. In NK cells it can act as an activating receptor on its own. This is the result of two splice variants, allowing association with KARAP/DAP12 as well as DAP10 (Lanier 2003). NKG2D can recognize a large variety of ligands distantly related to MHC class I, expressed mainly on certain stressed, infected, or transformed cells. The ligands for human NKG2D include MICA and MICB, expressed on stressed epithelial cells, and the CMV-encoded proteins ULBP1–3. Murine NKG2D binds to Rae-1 and HL-60 expressed by stressed cells and certain tumor cells, and a recently identified ligand termed mouse ULBP-like transcript-a (MULT-1) (Raulet 2003). The last appears to be constitutively expressed in many tissues. Structural studies of NKG2D co-crystallizing with its ligands have provided an explanation of how this receptor can bind to different ligands (see Figure 3) (Natarajan et al. 2002). NKG2D was initially thought to be completely independent of inhibitory signals; it now appears that these signals can inhibit activation of NKG2D, but less efficiently than other activating receptors (Pende et al. 2001). Stressed normal cells can therefore be killed through recognition by NKG2D even if they express considerable levels of MHC class I molecules. NKG2D and its ligands provide many exciting lines of research in infection and tumor immunology, discussed further in the specialized sections below.

ACTIVATING RECEPTORS WITH UNKNOWN SPECIFICITY, INCLUDING RECEPTORS RECOGNIZING NON-MHC MOLECULES ON NORMAL CELLS

The 'missing self' model postulates that the activating NK cell receptors recognize ligands on most normal cells. There is strong evidence that NK cells can indeed kill normal cells, which lack MHC class I, and which also lack the stress-induced ligands for NKG2D discussed previously. Thus, there must be other activating receptors. Some of the receptors discussed here play a role in the surveillance of normal cells, but it must be emphasized that the exact (combination of) receptors used in different situations remain to be clarified. One of the reasons for this may be that NK cells use several receptors in a parallel and redundant fashion, which makes it difficult to prove the role of one by targeting it genetically or in antibody blockade experiments. It is therefore interesting that several activating receptors were identified in an experimental approach with xenogeneic effector target cell combinations, in order to minimize the number of receptor–ligand pairs involved. Using this approach, antibodies binding to the three so-called NCRs, NKp30, NK p44, and NKp46, were identified (Moretta et al. 2001). All NK cells, in humans as well as in mice, express NKp30 and NKp46. The former is the main activating receptor in NK cell interactions with dendritic cells (Moretta 2002). NKp46 is involved in recognition of normal as well as many tumor cells, and there is also evidence that it can recognize influenza virus-infected cells via sialic residues of the hemagglutinin (Mandelboim et al. 2001). The level of NKp46 varies between NK cells, and this correlates with their cytotoxic potential. Only human activated NK cells express NKp44 (Moretta et al. 2001). Its ligands are unknown.

There is intensive ongoing research on the specificity and expression patterns of these activating receptors, as well as their role in recognition of various target cells. A frequently used strategy to define the specificity of receptors is to produce multimeric, soluble proteins to identify ligands in different types of cells. This is not always as straightforward as it sounds – the geometry and affinity of these constructs may not always allow ligand-specific binding above background levels. The final answer as to which activating receptors NK cells use in different situations must be based on methods allowing the direct measurement of ligands on target cells, as well as antibody cocktails combining different antibodies to completely block the critical interactions (Moretta et al. 2001).

Transduction and integration of signals after NK cell recognition

The ligation of activating and inhibitory receptors must be transduced to intracellular signals, and these must be integrated and read out to activate different NK cell programs. This is an intensive area of research, and only a fragmentary picture is currently available (Colucci et al. 2002; Lanier 2003). Upon ligation of inhibitory receptors, the phosphorylated ITIMs in their cytoplasmic tails recruit -SH2-domain-containing tyrosine phosphatase (SHP-1) and other phosphatases. These are thought to act on substrates that have been phosphorylated in the proximal part of activating pathways. There are multiple, parallel, proximal signaling pathways for activating receptors, which generally signal through noncovalently associated adaptor molecules. This association commonly involves an aspartic acid residue in the transmembrane region of the adaptor molecule, interacting with a positively charged amino acid in corresponding domain of the ligand-binding receptor. Some of the adaptor molecules, such as CD3ζ, FcεRIγ, and KARAP/DAP-12, contain ITAMs in their cytoplasmic tails. Ligation of an NK receptor linked to an ITAM-containing adaptor initiate proximal signaling events in a protein tyrosine kinase (PTK) cascade similar to ITAM-dependent mechanisms in T- and B-cell activation. It involves activation of PTK in the Src family, leading to activation of ZAP70 and Syk in the Syk PTK family (Colucci et al. 2002). DAP10, one of the adaptor molecules associating with NKG2D, lacks ITAMs (Lanier 2003). Its cytoplasmic tail instead contains the motif YINM, which can bind and activate phosphatidylinositol 3-kinase (PI3K) (Trinchieri 2003a).

Further downstream, additional intracellular adaptor molecules are activated, e.g. linker for activation of T cells (LAT), SLP 76, phospholipase Cγ (PLCγ1), PI3K, and Vav family members of guanine nucleotide exchange factors. Examples of receptors interacting with ITAM-containing molecules are CD16, NKp46, and NKp30, as well as the activating KIRs and Ly49Rs (Yokoyama 1999; Moretta et al. 2001; Colucci et al. 2003).

Table 4 summarizes the pathways known so far, including examples of interacting receptors, adaptor molecules, and some information on downstream signaling. The multiple pathways may just represent redundancy as a result of evolutionary tinkering, but it is also possible that they are needed to preserve hierarchies of interactions and specific consequences of certain interactions. As a result of these multiple, partly parallel pathways, specific defects caused by gene deletion or pharmacological intervention may in many cases have few if any consequences for overall NK function, whereas T- and B-cell function and even development may be severely affected. The highly NK-sensitive target cell YAC-1 is, for example, killed efficiently by mice with defects in Syk, ZAP70, or both (Colucci et al. 2002). One may speculate that this and other 'prototype' NK targets were once chosen initially as highly reliable for NK assays, just because they express multiple

activating ligands, although that was of course not known at the time. Some NK functions appear to rely critically on one pathway, e.g. Ly49H–KARAP/DAP-12, relevant for mouse CMV infection (Yokoyama and Plougastel 2003). Cytokines and adhesion molecules can also trigger or modulate NK function; this is regulated by pathways common to many white blood cells.

As more is learned about activating and inhibiting receptors, tools must be developed to dissect the complexity created by multiple inputs. Can all pathways interact and, if so, are the signals simply additive or subtractive? Are some activating receptors specialized in the sense that they are less (or not at all) influenced by inhibitory receptors, or activate only some effector function? This analysis will require imaging techniques to assess intracellular clustering of receptors and signaling molecules, as well as mathematical models for prediction and interpretation of the final outcome in effector function in response to different inputs. A few studies on inhibitory and activating immune synapses between NK cells and target cells have been published (Davis 2002). Although this field is just starting, it is clear that inhibitory receptors and their MHC class I ligands cluster in the center of the synapse in many situations.

Expression of NK receptors on T cells

Many of the NK receptors discussed above can also be expressed by subpopulations of T cells under certain conditions (Mingari et al. 2000; McMahon and Raulet 2001; Young and Uhrberg 2002; Trinchieri 2003a). One may indeed question the term NK receptors, which is usually based on the notion that the given receptor was first identified on NK cells. A detailed discussion is beyond the scope of this chapter, but an overview is integrated into Table 2. Suffice it to say that the function of these receptors is not clear; it has been proposed that these receptors can be used to fine-tune the action of T cells with respect to effector function, proliferation, survival, or homeostasis. A common theme is that they appear to act exclusively as co-receptors for activation or inhibition; they can thus act only by superimposing signals on those triggered via TCR recognition.

Polymorphism and complexity: implications for receptor repertoires, tolerance, and disease associations

As evident from the discussion of each NK receptor type, there are several levels of polymorphisms and complexity in this system. There are multiple genes encoding activating and inhibiting receptors within one individual. Some of these genes are present in all individuals and are conserved; some are present in all individuals, but with different alleles; some are expressed only in some individuals (Vilches and Parham 2002; Parham and McQueen 2003). Furthermore, within one individual, different NK cells express different combinations of receptors (Raulet et al. 2001; Hsu et al. 2002; Vilches and Parham 2002). Most of the mechanisms behind these patterns, as well as the functional implications, are unknown. In the following, the first section reviews a number of solid observations about NK repertoires. The next two sections deal with interpretations and hypotheses about this complexity, first in relation to tolerance development and then in relation to resistance against disease associations and evolutionary pressures.

DEVELOPMENT OF RECEPTOR REPERTOIRES

Natural killer cells acquire their MHC class I-specific receptors relatively late during ontogeny. The development of the receptor repertoire has been studied mainly in mice (Raulet et al. 2001). Some key observations from such studies are described below, with reference to human studies whenever there are similar or different data available.

The patterns with different combinations of receptors expressed by each NK cells arise from the basic notion that each receptor gene is either on or off in a given cell. This ‘variegated’ pattern of Ly49Rs and KIRs is determined at the gene expression level in a partly stochastic process. Some transcription factors influencing this process have been identified, but the detailed regulation remains unclear (Held et al. 1999). The receptor genes are usually, but not always, expressed in a monoallelic fashion, indicating that the stochastic mechanisms determining whether a particular gene is on or off apply to different loci as well as to different alleles at one locus. As a result, the proportion of cells in an individual that express a given receptor can vary between 5 and 80 percent. Expression of multiple different receptors on one cell follows the ‘product rule’. This means that the probability for simultaneous expression of two different Ly49Rs (as well as the KIRs) can be calculated by multiplying the proportion of cells that express each single receptor (Raulet et al. 2001).

The NK cells in a newborn mouse or human cord blood initially express NKG2A/CD94, but not Ly49Rs or KIRs. The Ly49Rs then appear sequentially in certain patterns, Ly49A usually preceding Ly49C and Ly49G2, but this order is not absolute. Interaction with MHC class I molecules on stromal cells influence this process (Roth et al. 2000), in a manner that is not well understood, but which reduces the number of cells expressing several receptors of the same specificity. After 3–4 weeks, the Ly49R expression has developed to the adult pattern, which means that each NK cell expresses at least one and often several receptors (Raulet et al. 2001).

Concurrently, the proportion of NKG2A-positive cells falls to approximately 50 percent in the mouse, whereas the majority of human NK cells express this receptor throughout life. Once established, the receptor expression of each cell appears stable. Long-term follow-up of human NK clones in vitro shows a similar pattern.

NK CELL REPERTOIRE IN RELATION TO AUTOLOGOUS MHC MOLECULES

Most NK cells have the potential to kill according to the 'missing self' model, i.e. their interactions with most normal cells are ultimately controlled by the inhibitory MHC class I receptors. As the latter, at least the ones in the KIR and Ly49R families, are allospecific, there is a risk for autoreactivity. How can 'tolerance' be ascertained in the system, given the complexity described above? Not only do receptors differ between individuals, and between NK cells within the individual, but in addition, the MHC class I ligands are extremely polymorphic and not genetically linked to the receptor genes. The ability to be triggered by activating ligands expressed by most cells must thus somehow be matched somatically with the expression of inhibitory receptors independently recognizing segregating ligands on autologous cells. How this is achieved has so far remained an enigma.

There are several theoretical possibilities. A simple positive selection model is based on stochastic expression of different receptor combinations in each NK cell, followed by a selection step in which only those receptors recognizing that at least one self MHC class I molecule during development receives a survival signal. Models based on this principle predict that the presence of a given MHC class I gene product should select for increased numbers of NK cells with this specificity. However, there is little or no influence at all of HLA on the KIR repertoire; in the mouse, H-2 has a minor influence on the frequency of NK cells with given Ly49 receptors, but in the opposite direction: the number of cells expressing a given receptor are marginally, but reproducibly, fewer if their ligands are present in the host. MHC class I-deficient mice therefore have somewhat more cells expressing any given Ly49R than normal mice (Raulet et al. 2001).

A second possibility, 'the sequential receptor expression' model, postulates that developing NK cells express and test receptors against the environment in sequential and cumulative order, in a process that is terminated as soon as one receptor detects self-ligands in the environment. This predicts a reduced probability for expression of multiple different receptors, which can recognize the same ligand in each NK cell. There is supporting evidence for this in normal mice as well as in transgenic mice where one receptor is forced on the whole NK cell population. The mechanisms limiting expression of several receptors for the same self-ligand appear to act late in differentiation in an interaction between NK cells and stromal cells. It may represent a way to render NK cells as 'useful' as possible, because limited inhibitory receptor expression specific for any MHC product would lead to more sensitive detection of cells in which this particular product is partly down-regulated (Raulet et al. 2001; Salmon-Divon et al. 2003).

Despite these observations, the complete available data do not fit the simplest form of the sequential receptor expression model, which would predict that all NK cells in MHC class I-deficient mice or humans should express all inhibitory receptors (and this should still not be sufficient for tolerance). However, these individuals have normal numbers of NK cells, which display the usual variegated expression pattern of Ly49Rs and KIRs, and which are tolerant to autologous cells (Raulet et al. 2001). They retain other cytotoxic NK functions against certain tumor cells and antibody-coated target cells in antibody-dependent cell-mediated cytotoxicity (ADCC) assays.

It must thus be questioned whether tolerance is based solely on inhibitory, MHC class I-recognizing receptors. In the human, complete analysis of in vitro cultured NK clones from a few individuals indicate that each NK cell expresses at least one self-receptor (Valiante et al. 1997). To be conclusive as to whether inhibitory receptors can account for tolerance, corresponding studies must be done on freshly derived cells. These have so far been performed only in mice, and always reveal a fraction of cells where no known self-receptor is expressed (Raulet et al. 2001). However, it can be argued that this observation is also inconclusive until there is a complete panel of receptors identified (and the corresponding reagents).

The currently most accepted, modified model is based on the idea that the sequential receptor expression of inhibitory receptors is only one of several contributing to tolerance, and that it acts only during a limited time window in differentiation. It would therefore not allow expression of all receptors in one NK cell. Additional mechanisms to consider in conjunction with this model, or independently, are those that do not rely on inhibitory MHC class I-specific receptors. Some NK cells could thus acquire tolerance by expression of another type of inhibitory receptor(s), or by down-regulating the receptors or critical links in signal transduction pathways that are responsible for the initial activation in missing self-recognition (Held et al. 2003).

It should be possible to identify these mechanisms by comparative transcriptomic or proteomic profiles on NK cells from mice that differ only in one MHC class I allele (and, hence, NK cell tolerance to cells that lack this allele). The most dramatic influence of MHC type on NK receptors observed so far is a down-regulation of Ly49R (by 30–90 percent) when their high-affinity ligands are present in the host (Olsson et al. 1995; Raulet et al. 2001). This appears to result partly from a direct, post-translational response to interaction with the

ligand, most probably leading to internalization or shedding of the receptor. It has not been observed with the KIR in humans. Although this down-regulation leads to enhanced sensitivity to detect impaired expression of the corresponding allele, potentially making the NK cell more 'useful', the functional significance of this phenomenon is unclear. Finally, there is evidence that the receptor levels of NK cells are influenced by the ligand expression of the NK cell itself (Kase et al. 1998; Doucey et al. 2004). This has led to speculations that Ly49Rs can interact with their ligands in '*cis*', and that this may be involved in regulation or tolerance (Held et al. 2003).

Whether tolerance is based on alteration of activating or inhibitory pathways, one must finally consider whether it is irreversible, or whether mature NK cells can alter their specificity once they are mature. In mice with mosaic MHC class I expression where a part of the cells lacked one self-allele out of three expressed by the remaining cells, NK cells were nonreactive to both MHC class I phenotypes but retained the ability to kill cells lacking all MHC class I alleles (Johansson et al. 1997). When NK cells of the two MHC phenotypes were separated and cultured in IL-2 in vitro, the ones with complete expression of three alleles acquired the ability to kill the cells expressing only two alleles. Although this demonstrates that some tolerant cells are preserved and not deleted, it remains to be investigated whether tolerance is actually reversible in vivo.

In summary, it seems plausible that NK cells acquire tolerance by a combination of mechanisms influencing activating as well as inhibiting mechanisms. This can be manifested at the level of gene expression, but post-translational mechanisms, where the cellular distribution and even membrane topology for receptor expression patterns influence the specificity, are not excluded. Further research is required to understand the general principles behind the development of receptor repertoires and tolerance in the NK system.

NK RECEPTOR GENES: EVOLUTIONARY ASPECTS AND IMPLICATIONS FOR DISEASE ASSOCIATIONS

Figure 4 provides a schematic overview of the two major families. The activating and the inhibiting receptors in the NKG2 family have been largely conserved. The mouse has four genes in the Nkrp1 family, the human only one (Yokoyama and Plougastel 2003). There are several other more or less related genes encoded in the NKC, such as CD69, an early activation marker for lymphocytes, including NK cells. The NK cells in these two species, as well as in the rat, are thus similar in many respects. However, there is a dramatic difference in the expansion of the Ly49 family in the mouse and rat. The Ly49L gene in humans does not encode a functional product, and this gene family therefore plays no role in humans.

The human genome instead contains the gene families in the LRC on chromosome 19 (Figure 4) (Trowsdale et al. 2001). For both KIR and Ly49R families, there is considerable polymorphism and evidence that they undergo rapid evolution – the KIRs may even be evolving at a higher pace than human MHC genes (Kane et al. 2001; Hsu et al. 2002; Vilches and Parham 2002). It is believed that infectious agents drive this evolution, although the mechanisms are not well understood. One key to the problem may lie in the function of the MHC class I-specific activating receptors in each family, which, at least in humans, are the genes that show the highest diversity. It has been proposed that their specificity goes beyond MHC class I molecules, and that they may recognize pathogen-encoded ligands, either in association with MHC molecules or by themselves. The latter is certainly the case for the activating Ly49H receptor in the mouse, as discussed in the section on CMV.

The considerable polymorphism and dynamic evolution of the KIR genes in the human population opens the possibility for studies of disease associations. Individuals differ in the number of loci as well as the alleles carried by these loci. Certain typical 'haplotypes' (combinations of loci and their respective alleles) are now being defined, and observed to be present in different frequencies in different ethnic groups (Hsu et al. 2002; Parham and McQueen 2003). Do different genes or haplotypes affect the incidence or course of infectious, malignant, or autoimmune diseases and is there an impact on the outcome of transplantation? Some associations, open for different mechanistic interpretations, have been reported (Table 5) and more are probably waiting in the wings in this intensive research field.

NK CELLS IN INFECTIONS

Virus infections

CLINICAL OBSERVATIONS

The picture emerging from the study of natural infections and their correlation with impaired NK activity in patients suggests that NK cells may be particularly important for the defense against viruses in the herpes family (Biron et al. 1989; Cerwenka and Lanier 2001; Orange et al. 2002). These have in common that they remain latent with no or little viral replication after the primary infection; they may be reactivated and cause opportunistic infections under conditions where the immune system is compromised, e.g. in malignant or infectious diseases and transplantation. This group includes, among others, varicella-zoster virus (VZV), herpes simplex type 1 virus (HSV-1), Epstein–Barr virus (EBV), and HCMV. The evidence is often anecdotal and sometimes difficult to interpret, because impaired

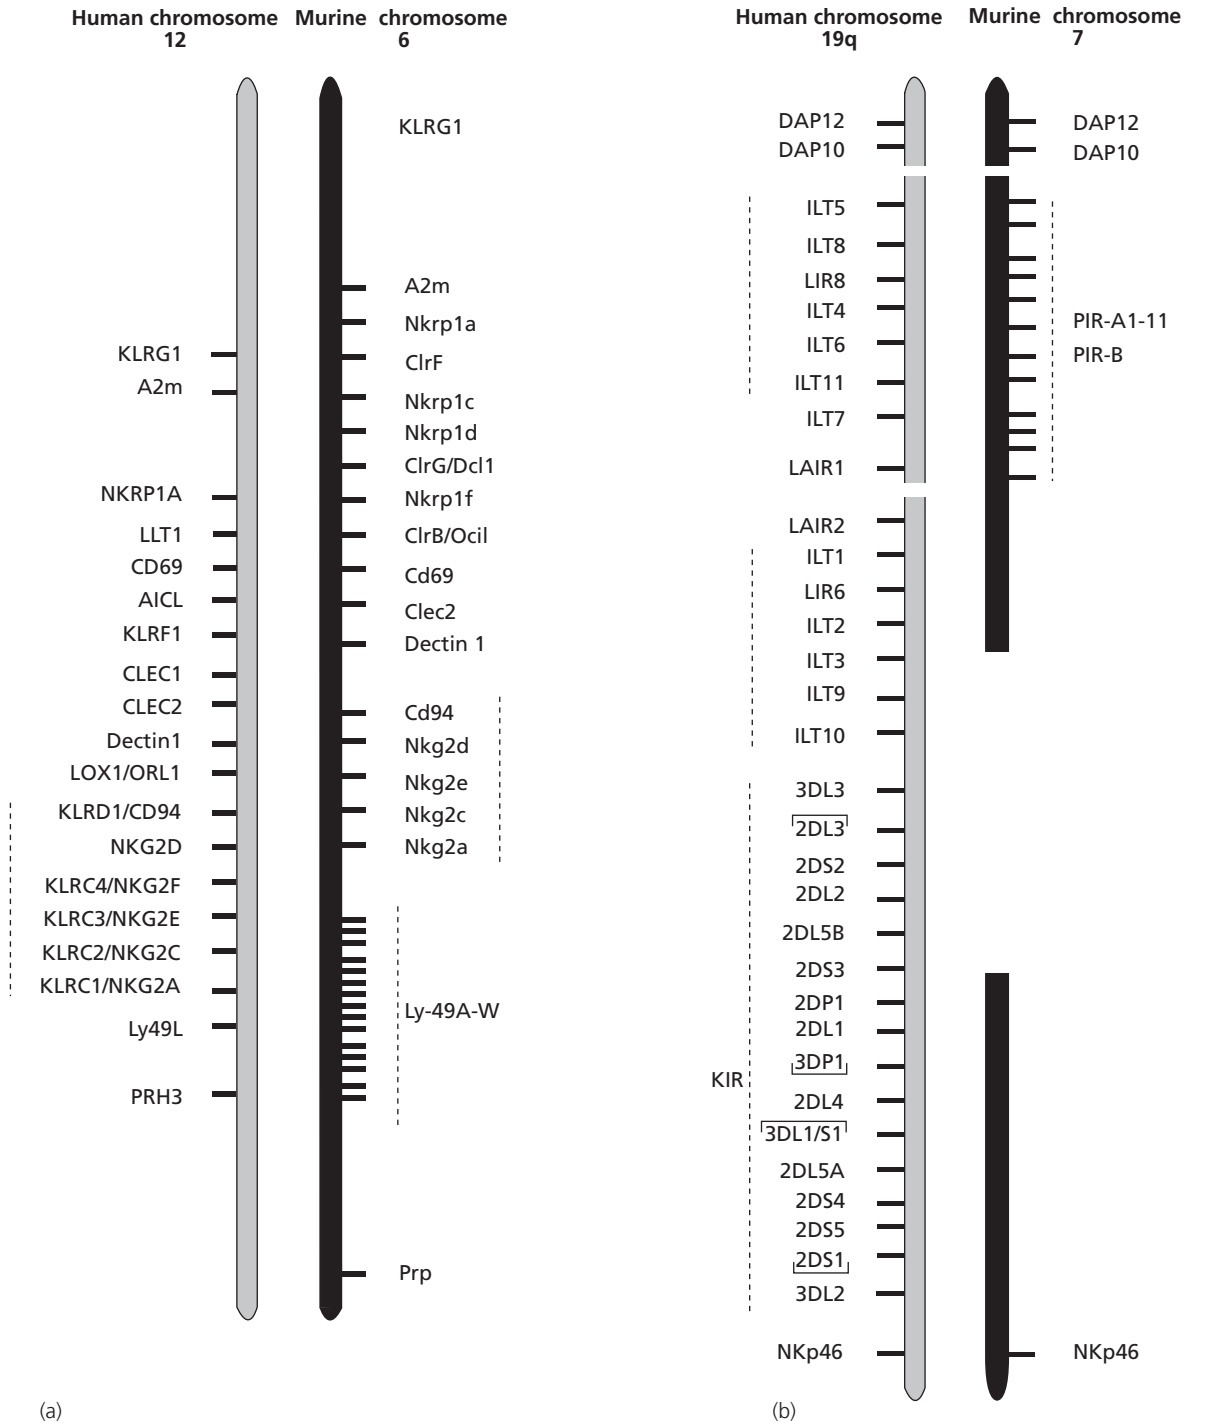

Figure (a) *The natural killer (NK) gene complex (NKC) and* **(b)** *the leukocyte receptor cluster (LRC). The NKC is present on human chromosome 12p13.1 and mouse distal chromosome 6 whereas the LRC is on human chromosome 19q13 and mouse chromosome 7 (Trowsdale et al. 2001; Hsu et al. 2002; Yokoyama and Plougastel 2003). Dashed vertical lines denote the NKG2/CD94-, the Ly49-, the LIR/ILT-, the PIR-, and the KIR-gene families. The brackets comprise the variable KIR gene regions, opposed to the three conserved framework genes* 3DL3, 3DL2, *and* 2DL4 *(Vilches and Parham 2002). Positions of genes are not drawn to scale.*

NK cell function may be the nonspecific consequence of infectious disease rather than its specific cause. Furthermore, NK deficiency is usually relative rather than absolute, and often associated with other immune defects. A typical example is the X-linked lymphoproliferative syndrome (Moretta et al. 2001), resulting from defective control of EBV, which is associated with perturbed function of NK cells as well as of T cells as a result of a defect in the signaling lymphocyte activation molecule-associated protein (SAP), involved in regulation of the signaling lymphocyte activation molecule (SLAM) pathway.

Table 5 *Killer cell immunoglobulin receptor (KIR) polymorphisms and disease associations*

KIR	Disease association
KIR3DS1	HLA-Bw-80Ile^{+} HIV-1-infected individuals – delayed progression to AIDS
	In case of HLA-Bw-80Ile absence KIR3DS1 is associated with more rapid progression (Martin et al. 2002a)
KIR2DS2	Development of rheumatoid vasculitis associated with 2DS2^{+} CD4^{+} CD28^{null} T cells (Namekawa et al. 2000)
KIR2DS1, KIR2DS2	Associated with psoriatic arthritis, but only when the HLA ligands for their homologous inhibitory receptors were absent (Martin et al. 2002b)
KIR2DS2	Susceptibility to develop type 1 diabetes when present with group 1 HLA-C ligands (van der Silk et al. 2003)

There is an often cited example of an NK-deficient patient that is particularly informative (Biron et al. 1989). A 13-year-old girl presented with an unusually severe chickenpox (varicella) infection. She was found to have a complete and selective lack of NK cells. Other cells of the innate immune system were normal, and so were T- and B-cell responses, which eventually resolved the infection. Within 5 years, she developed first a severe HCMV infection and then a disseminated HSV-1 infection. Siblings and relatives showed normal NK cell development and function, and the mechanism behind this immune defect remains a mystery. Such total and selective NK cell deficiency is apparently extremely rare, and one may ask why. It may be that it is usually lethal in the intrauterine or early postnatal period. Another possibility is simply that it requires a combination of genetic defects for which the probability is extremely low. For future research it may be important to identify patients with more discrete effects, e.g. patients who retain a normal or close to normal NK cell number that, however, lacks one or more receptor or effector functions.

Patients with human immunodeficiency (HIV) infection and/or acquired immune deficiency syndrome (AIDS) represent one of the most well-studied patient categories in clinical immunology laboratories. A consistent pattern in these patients is that NK cell activity is reduced (Scott-Algara and Paul 2002). This can occur relatively early in infection, and often without diminished NK cell numbers in the blood. The functional defect appears more prominent for the direct NK cytotoxicity than the ADCC activity mediated through a FcγRIII receptor. There may be an association with reduced expression levels of the activating receptors NKp30 and NKp46 (De Maria et al. 2003; Mavilio et al. 2003). NK cells may contribute to various defense mechanisms, including production of chemokines blocking co-receptors for viral infection; NK cells may also be important for control of human herpesvirus 8 (HHV-8) and Kaposi's sarcoma (Cerwenka and Lanier 2001). The Nef gene product of the virus down-regulates HLA-A and -B expression, but does not affect HLA-C and -E molecules, ligands for the inhibitory NK receptors KIR2D and NKG2A (Cohen et al. 1999; Cerwenka and Lanier 2001; Mavilio et al. 2003).

EXPERIMENTAL STUDIES

The role of NK cells has been studied in a variety of animal models, mainly in mice, and usually by depleting the NK cells before injection of a relatively high dose of pathogenic virus. Normal mice respond with increased NK cell activity, locally and systemically, to most if not all viruses 2–4 days after infection (Tay et al. 1998; Biron et al. 1999). Early cytokines, particularly type I interferons and IL-12, are important factors for this rapid augmentation of NK activity. In some virus infections, such as MCMV, Pichinde virus, HSV-1, influenza virus, Coxsackie virus, vaccinia virus, ectromelia virus, encephalomyocarditis virus, and Theiler's virus, the early NK defense is crucial. NK cell-depleted mice show dramatically increased viral replication locally or systemically (Biron et al. 1999). Depending on the infection dose and the virus, the NK cell-depleted mice may die within one week, whereas normal mice limit the replication and survive until the adaptive T- and B-cell response reaches effective activity and clears the infection. As discussed in more detail in relation to MCMV, NK cells contribute to early defense by direct killing of infected cells, as well as by secretion of chemokines and cytokines, particularly IFN-γ (Biron et al. 1999).

With other viruses, NK cell depletion has no effect on the course of the infection, even though there may be strong initial augmentation of NK cell activity. A typical example in this category is lymphocytic choriomeningitis virus (LCMV), which otherwise is extremely sensitive to immune mechanisms and cytotoxic T cells (Tay et al. 1998; Biron et al. 1999). The reasons why certain viruses are 'NK insensitive' are not known. It may relate to whether NK cells can specifically target the virus-infected cells. Antiviral NK cell-mediated defense through cytotoxicity implies that NK cells should be able to recognize the infected cells and specifically eliminate them. In many cases, virus-infected human or murine cells are more NK susceptible than non-infected controls, but this is not a general rule. For certain viruses, infected cells may even become more resistant. Viruses may affect NK sensitivity by a variety of molecular mechanisms, including reduced MHC class I expression, leading to killing by recognition of 'missing self'. There is good evidence for this in the

case of HSV-1- and vaccinia virus-infected cells (Orange et al. 2002). The pattern with HCMV and MCMV, known to possess multiple mechanisms for interference with the MHC class I pathway, is more complex, as discussed in detail below.

NK CELLS IN CMV INFECTION: MOLECULAR ASPECTS OF RECOGNITION, EFFECTOR FUNCTION, AND ESCAPE

MCMV and HCMV are the most well-studied infections with respect to NK cells, and several interesting molecular mechanisms have been revealed. These closely related viruses are therefore discussed in more detail, as an example of the complex pattern that may emerge in co-evolution of host and virus. HCMV and MCMV establish latent infections, and their large DNA-based genomes encode many proteins that are not required for replication in host cells in vitro, but act instead to modulate and interfere with host immune responses, including NK cells.

Mice with NK cell deficiency caused by low age, experimental depletion, or gene defects are highly sensitive to experimental infection with MCMV (Tay et al. 1998; Lee et al. 2002). Adoptive transfer of NK cells can restore resistance. NK cells appear to mediate their effect by at least two mechanisms: perforin-dependent cytotoxicity, which is the more important mechanism in the spleen, and IFN-γ secretion, which is crucial to limit viral replication in the liver (Biron et al. 1999; Lee et al. 2002). The cytotoxic response depends on type I interferons acting through the STAT-1 signaling pathway in NK cells, whereas the cytokine response depends on IL-12 produced by macrophages and acting through STAT-4 (Biron et al. 2002). IFN-γ can exert its effect directly on hepatocytes to limit viral replication, but may also act by stimulating macrophages for inducible nitric oxide synthase. There is thus an important crosstalk between NK cells and macrophages in the liver, emphasized also by a crucial role of the macrophage-secreted chemokine macrophage inflammatory protein 1-α (MIP-1α) for NK cell migration into the liver during infection (Lee et al. 2002).

How can NK cells target CMV-infected cells? Given that both HCMV and MCMV possess several different genes for interference with the MHC class I pathway, NK cells are important innate effector cells against infection in both species, and the particularly strong CMV resistance in the mouse strain C57Black has for a long time been shown to map to a locus within or close to the Ly49 family (CMV1), it has been speculated whether 'missing self' recognition plays an important role (Lee et al. 2002). However, C57Black mice deficient for MHC class I molecules, the NK cells of which cannot perform missing self-recognition, show a strong NK-mediated resistance to the infections. Research in recent years has instead identified the activating Ly49H receptor as the product of the CMVR1 locus (Yokoyama and Scalzo 2002). Resistance is impaired in mice treated with Ly49H antibodies, and in mice deficient in the adaptor molecule crucial for Ly49H signaling, KARAP/DAP12 (Sjolin et al. 2002; Yokoyama and Plougastel 2003). The Ly49 receptor acts by recognizing the virus-encoded, GPI membrane-attached molecule m157 on infected cells (Arase et al. 2002; Smith et al. 2002). This viral gene, which shows distant homology to MHC class I genes, is not required for virus replication in vitro, and one may wonder why and how the virus has evolved it, because it acts to limit spread of the virus. An attractive model proposes that m157 evolved as a ligand to target the inhibitory MHC class I-recognizing receptor Ly49I (Yokoyama and Scalzo 2002), thereby allowing the virus to escape missing self-recognition in spite of its interference with host cell MHC class I molecules. The Ly49H receptor would represent the evolutionary countermove of the host, resulting in the selection of a receptor gene where recombination and other mechanisms would have maintained recognition of m157, but not of host MHC class I molecules, and switched the intramembrane/cytoplasmic domains to convey activating rather than inhibiting signals.

This scenario may be difficult if not impossible to test, but it has profound implications for our understanding of infections as an evolutionary pressure for the NK cell system. MCMV carries at least half a dozen additional genes encoding distant MHC class I homologs (Yokoyama and Scalzo 2002), the function of which remain to be determined. Similarly, mice as well as humans have a number of activating MHC class I receptors in the Ly49 and KIR families with poorly understood function (see Table 2). It may be that the inhibitory MHC class I-specific receptors provide a platform for development of viral escape strategies that can easily be turned into counter-weapons in the next host, or in the next evolutionary step. The intensive research on activating KIRs, and their possible association with diseases (Martin et al. 2002a, b; Namekawa et al. 2000; van der Slik et al. 2003) (Table 5), may give important clues in this research field.

One may still ask why CMV interference with MHC class I recognition is not sufficient to induce NK cell susceptibility. This is probably a result of a variety of parallel viral mechanisms that interfere with NK cell recognition and triggering (Figure 5). MCMV and HCMV both possess genes, *UL16* and *m152* respectively, the products of which bind to and prevent cell surface expression of ligands for the activating NKG2D receptor, such as MIC, ULBP1 and -2 in humans, and Rae-1 and H-60 in mice (Cerwenka and Lanier 2001; Krmpotic et al. 2002; Orange et al. 2002; Dunn et al. 2003; Lodoen et al. 2003; Rolle et al. 2003). Even if the NKG2D receptor is not believed to be the primary activating receptor for 'missing self' surveillance of normal cells, there is evidence that the activating ligands of this

receptor, which are induced during HCMV infection, play a more prominent role for NK cell recognition of infected cells. This implies that the virus in parallel down-regulates the activating ligands that are important in normal cells, but, as these are not completely known, this hypothesis remains to be tested.

Furthermore, the HCMV gene *UL40* provides a signal sequence that can bind to and promote expression of HLA-E, which may counteract the reduced expression of this ligand for the inhibitory NKG2A receptor caused by HCMV products that interfere with TAP function (Braud et al. 2002; Orange et al. 2002). HCMV also contains the gene *UL18*, which binds to the LIR-1 receptor on NK, B and dendritic cells with 1000-fold higher affinity than MHC class I molecules (Chapman et al. 1999). The UL18 protein has been proposed to act as a decoy ligand that inhibits NK cells (Reyburn et al. 1997), but this is controversial and the pathophysiological role of this viral product is not clear (Orange et al. 2002).

The overall picture emerging in the case of CMV is that the NK cell defense is important, because the virus has evolved different mechanisms to avoid it. The recognition strategy of NK cells with multiple activating and inhibitory receptors has probably emerged in dynamic co-evolution with CMV and other infectious agents, and it continues to provide a complex platform for ongoing evolution where activating and inhibitory receptors and their ligands interact.

Bacterial infections

Several effector functions of NK cells contribute to antibacterial responses. Granulysin, a membrane-perturbing peptide component of human (but not mouse) NK cell granules, is directly active against gram-positive and gram-negative bacteria, including *Mycobacterium tuberculosis* (Krensky 2000). NK cells can also lyse target cells infected with bacteria, e.g. *Shigella*, *Listeria*, *Salmonella*, *Legionella*, and *Mycobacterium* spp. (Bancroft 1993; Yokoyama 1999). Finally, by secretion of IFN-γ, they can activate macrophages and induce more efficient intracellular and extracellular elimination of bacteria, e.g. through reactive oxygen metabolites and reactive nitrogen intermediates. As IFN-γ can also deviate the ensuing adaptive response toward a Th1 type, NK cells cannot contribute only to early innate resistance; they also provide a link to adaptive responses against bacteria. In this context, one may also note that NK cells interact efficiently with dendritic cells (DC) (Moretta 2002; Zitvogel 2002). Upon infection with *M. tuberculosis*, DCs develop the capacity to activate NK cells, but they also become resistant to NK cell attack. The activated NK cells can, however, kill uninfected, immature DCs. This process, which involves altered expression levels of DC ligands for the NKp30-activating receptor and NKG2A-inhibiting receptor, may be important for optimal antigen presentation to T cells.

Although depletion of NK cells in experimental infection in mice led to enhanced growth of *Mycobacterium avium* (Florido et al. 2003), there is so far no model where NK cells have an absolutely critical role in immunocompetent animals. This is presumably because numerous partly overlapping mechanisms cooperate in antibacterial resistance. In several infections, the contribution of NK cells is most clearly recognized in the absence of one or more other immune components. A well-studied example is resistance to *Listeria monocytogenes* in SCID mice (Bancroft 1993). NK cells are critical for the early limitation of bacterial spread. Under the influence of IL-12 and other cytokines produced by infected macrophages, NK cells are induced to secrete IFN-γ, which in turn activates the macrophages. Their induced antibacterial pathways can limit the spread of bacteria, but T cells are required ultimately to resolve the infection. Similar schemes can be drawn for several other intracellular bacteria, e.g. *M. tuberculosis*.

It is also uncertain whether there is a particularly prominent role for NK cells in any disease in the clinical panorama. Bacterial infections, particularly in the respiratory tract, have been reported in certain patients with defects of dysregulation of NK cells, but it cannot be excluded that these reflect secondary infections

Figure 5 *A consensus model for the role of natural killer (NK) cells in infections. During infection NK cells can be activated either directly by recognition of microbial components or indirectly by cytokines (interferon IFN-αβ, interleukin IL-12) produced from infected cells or activated macrophages (Mϕ) (Biron et al. 1999; Trinchieri 2003b). The interaction with immature dendritic cells (iDC) encountering antigens or pathogens leads to reciprocal activation, driving, on the one hand, maturation of DCs, which is crucial for induction of the adaptive immune response, and, on the other, NK cell activation (Moretta 2002). This is accompanied by strong NK cell-derived IFN-γ production, most probably IL-15-driven NK cell proliferation and ordered NK cell recruitment to the site of infection, which is orchestrated by chemokines. Although IFN-γ is crucial for induction of a variety of defense programs exerted by macrophages and also somatic cells, NK cells contribute to pathogen destruction by cytotoxic mechanisms. Missing or altered self as a consequence of pathogen invasion can be recognized by NK cells and induces killing of the infected cell. The elaborate interplay between NK cells and* murine *or* human cytomegalovirus *(MCMV and HCMV) is illustrated (Cerwenka and Lanier 2001; Braud et al. 2002; Orange et al. 2002). The virus interferes with MHCI surface expression (m04, -06, -152; US2, -3, -4, -6, -11), expresses MHCI-like surrogates (m144, m157, UL18), and interferes with surface expression (m152, UL16) of cellular 'stress'-indicative molecules (H60, Rae-1, MIC-A/B, ULBP). The viral MHCI-like m144 protein binds to an unknown inhibitory receptor, whereas the viral m157 protein is recognized by the activating Ly49H receptor, which significantly contributes to resistance against MCMV in certain mouse strains (Arase et al. 2002; Smith et al. 2002). Cells expressing 'stress'-indicative molecules (*altered SELF*) are recognized via the activating receptor NKG2D (Raulet 2003).*

complicating an initial viral disease (Orange et al. 2002). The lack of evidence for an essential role of NK cells or any other innate component in an infection does not mean that these are unimportant. There are large individual variations in the severity of initial disease developing before the sterilizing adaptive responses step in. Future research in bacterial diseases will address this if such patterns can be correlated to selective defects of, for example, NK receptor pathways.

Upon bacterial infection, NK cells may not only become activated indirectly via cytokines secreted by macrophages and DCs. Cognate interactions involving the sensing of reduced MHC class I expression of infected macrophages may occur with *Salmonella*, *Yersinia*, and *Chlamydia* spp. (Kirveskari et al. 1999). Through the Toll-like receptor 9, NK cells can be directly activated by unmethylated CpG sequences in bacterial DNA (Ashkar and Rosenthal 2002). There is also evidence that human NK cells can use the activating NKp46 receptor to directly recognize and kill *M. tuberculosis*-infected monocytes, without concurrent down-regulation of MHC class I molecules (Vankayalapati et al. 2002). The future research on NK cells may well identify several direct molecular recognition pathways for bacteria or bacteria-infected cells.

PARASITE INFECTIONS

The parasites represent a very heterogeneous group of organisms. Nevertheless, common patterns emerge with respect to the role of NK cells in infections, some resembling those seen with NK responses to intracellular bacteria (Figure 5). Infected human or murine hosts often show an early augmentation of NK cell activity, e.g. in toxoplasma, leishmania, and trypanosoma infection (Scott and Trinchieri 1995). This activation is partly indirect via cytokines such as IL-12 and TNF-α secreted by infected macrophages. In addition, there is evidence for direct recognition of parasites, their products or infected cells. Human NK cells can be stimulated by the leishmania lipophosphoglycan via Toll-like receptor 2 (Becker et al. 2003), and they can also recognize *Plasmodium falciparum*-infected erythrocytes by a so far unknown receptor (Artavanis-Tsakonas and Riley 2002). Apart from activation, there may also be local recruitment of NK cells; these represent the second wave of infiltrating cells (after granulocytes) at the site of leishmania infection in mice.

As a consequence of activation, NK cells can secrete cytokines to stimulate macrophage-mediated elimination of intracellular and extracellular parasites. Leishmania antigens can also induce a proliferative response of NK cells in vitro. Furthermore, activated NK cells can destroy infected host cells as well as extracellular parasites, e.g. tachyzoites of *Toxoplasma gondii* and trypomastigotes in Chagas' disease. As with many intracellular bacteria, IFN-γ appears to be a key cytokine (Cardillo et al. 1996), even if clear evidence for the in vivo role of NK cells may require models where other components are defective. Infection of mice with *T. gondii* may serve as an example. In β_2-microglobulin-deficient mice, with defective T-cell responses, there is a strong proliferative response of NK cells (Denkers et al. 1993). These eventually become the dominating cell population in the spleen and secrete high levels of IFN-γ, acting to limit the infection. IL-15 may play a role for this expansion of the NK cell population. In immunocompetent mice, NK cells contribute to the IFN-γ response, as do $CD8^+$ T cells, which are required to clear the infection.

As with other microorganisms, one focus of future research will be the identification of parasite structures that can be directly recognized by activating (or inhibiting) receptors of NK cells. Parasites represent a particular challenge in such studies, given their complex life cycles, with extracellular and intracellular stages, and in several cases also mechanisms for antigenic variation.

NK CELLS IN CANCER

Natural killer cells were discovered by virtue of their capacity to kill cancer cells. Furthermore, it was the correlation between strong NK activity and resistance to tumor transplants in mice that stimulated further interest in the field, at the early stage when this cytotoxic activity was frequently questioned as an in vitro artifact. There is now overwhelming evidence from animal models that NK cells can reject transplantable tumors of various histological types (Smyth et al. 2002). As expected from an innate nonadaptive mechanism, NK cell effects operate early, within hours to days of tumor inoculation, and they can be overruled by increasing the dose of transplanted tumor cells (Riccardi et al. 1979; Kärre et al. 1986; Smyth et al. 2002).

In some situations, the NK resistance is particularly efficient. These include host tumor combinations allowing 'missing self' recognition of the tumor, e.g. a F1 hybrid or transgenic host expressing MHC class I molecules that are not present in the tumor (Kiessling et al. 1975c) (discussed further below), or grafts of tumor cells with impaired MHC class I expression (Kärre et al. 1986; Smyth et al. 2002). However, efficient rejection can take place with, as well as without, alterations of the MHC phenotype of the tumor, e.g. the murine lymphoma RMA is not efficiently rejected by NK cells in the autologous C57Black strain. Strong rejection is, however, seen with sublines of the lymphoma such as RMA-S, selected for reduced MHC class I expression, as well as with sublines with normal MHC class I expression, but transfected with Rae-1, the ligand for the activating NKG2D receptor (Kärre et al. 1986; Raulet 2003). Other tumor lines are rejected because they

express Rae-1 constitutively. Furthermore, NK-mediated resistance is most efficient in models assessing hematogenous metastasis, usually to the lungs (Hanna 1982; Smyth et al. 2002). This correlates with the rapid NK cell-mediated elimination that can be observed in the lungs in short-term in vivo assays with isotope- or fluorescence-labeled tumor cells. Rapid, perforin-dependent cytotoxicity is thus a major, but not the only, mechanism in tumor cell rejection by NK cells. In its absence, Fas ligand-dependent killing can be observed, even though it is slower and appears less efficient in terms of the number of tumor cells that can be cleared (Screpanti et al. 2001; Wallin et al. 2003). It has also been proposed that NK cells can interact in concert with adaptive response mechanisms in tumor immunity. One obvious example is ADCC. NK cells can exert antitumor effects via this mechanism, at least in situations where monoclonal antibodies are used for treatment (Ravetch and Bolland 2001; Smyth et al. 2002). Another possibility is that early NK cell killing of tumor cells can promote antigen uptake and presentation by DCs, which will lead to more efficient T-cell responses.

There is limited information on the capacity of NK cells to eliminate primary tumor cells in the autochthonous host, as a result of the lack of good experimental models. Transgenic mice developing certain types of tumors at high frequency may become a useful tool here. It is clear that normal NK cell-defective mice to not develop spontaneous tumors in dramatic excess, arguing against classic immunosurveillance as the major function of NK cells. This does not exclude that they may be exploited for cancer therapy. Clinical studies may provide more answers in this context. The NK activity of cancer patients is often weakened. This observation is, however, difficult to interpret – it may simply reflect a consequence of advanced disease.

Adoptive transfer of NK cells was an inherent part of clinical trials with LAK cells performed during the 1980s. These were based on activation and expansion of lymphocytes from cancer patients in vitro, in medium containing relatively high doses of IL-2 (Rosenberg 1988; Smyth et al. 2002). Reinfusion of the cells led to documented shrinkage of tumor deposits in a minor part of the patients, and anecdotal dramatic responses. The available evidence suggests that NK cells were the dominant effector cells in the heterogeneous LAK cell populations, in the human as well as in the murine models providing the platform for this therapy (Whiteside et al. 1998; Wu and Lanier 2003). The therapy was abandoned as a result of limited efficacy, considerable safety problems with severe side effects often requiring intensive care, and development of novel cytokine modalities. However, these efforts demonstrated that activated, expanded, and reinfused NK cells could exert some antitumoral effects in a clinical setting, an important milestone. This has led to several protocols to activate and/or transfer NK cells for cancer therapy. In today's perspective, it is clear that many protocols are based on quite nonspecific stimulation of the NK system, with little attention being paid to specificity and tumor phenotype. In the future, it is reasonable to expect new modalities based on advances in understanding the molecular aspects of NK recognition, e.g. it has recently been reported that colon cancer cells may not only express the NKG2D ligand MICA, but may also shed this molecule in the circulation, where it can block recognition as well as down-modulate the activating NKG2D receptors (Salih et al. 2002). In future studies it may be more critical to assess that the tumor and NK cells in trials express the correct receptor–ligand pair, and take action to diagnose and remove soluble blocking factors. Another example where (mis)matching for missing self-recognition can be used to obtain antitumor effects is discussed below.

NK CELLS IN TRANSPLANTATION

The first thorough studies of an in vivo phenomenon associated with NK cells, at least with respect to genetics, was initiated more than 10 years before the discovery of the NK cells themselves. In the 1960s, it was recognized that lethally irradiated mice, whose adaptive T- and B-cell responses had been abrogated, could still reject MHC-mismatched bone marrow grafts. The mismatch combinations included not only completely allogeneic grafts (A/A rejecting B/B) but also parental grafts into F1 hybrid hosts (A/B rejecting B/B). The latter combination should not lead to T-cell-mediated rejection according to the classic transplantation laws, and this type of rejection was coined as 'hybrid resistance' (Cudkowicz and Bennett 1971). It was also demonstrated against tumor grafts and, in the rat, against grafts of normal lymphocytes. On the discovery of NK cells, it was soon demonstrated that they are the effector cells behind this peculiar type of rejection (Kiessling et al. 1977; Barao and Murphy 2003).

Natural killer cell-mediated rejection of allogeneic and parental grafts is controlled by the MHC region, but it was initially believed that MHC class I molecules were not involved. One major model proposed a new type of recessive, MHC-linked hemopoietic histocompatibility (Hh) locus (Yu et al. 1992). Today, the phenomena are interpreted within the paradigm of MHC class I receptors on NK cells, and missing self-recognition in particular: a graft of MHC type B/B lacks A alleles expressed by an allogeneic A/A as well as an F1 A/B host. NK cells with an inhibitory receptor for A may therefore not be inhibited by the B/B graft, leading to rejection (Kärre 1985; Kärre et al. 1986; Barao and Murphy 2003). Strong evidence for this has been provided by studies of mice made transgenic for a new MHC class I allele (the NK cells of which reject bone marrow from wild-type cells) and mice with deficient MHC class I expression (the bone marrow of which is rejected by NK cells from

wild-type mice) (Ohlen et al. 1989; Bix et al. 1991). However, missing self-recognition does not dominate in all combinations; NK cells can also use activating MHC class I-recognizing receptors to recognize an allogeneic graft, and this is the dominant mechanism in certain combinations (Nakamura et al. 1999; Smyth et al. 2002). The role of NK cells in rejection of organ grafts, where rejection is observed only in allogeneic, and not F1 anti-parental, combinations is less clear. They can infiltrate transplanted kidneys and hearts, and it has been proposed that they may attack allogeneic cells; alternatively they may regulate the T-cell responses that are initiated.

It is not clear whether recipient NK cells can affect the outcome of hematopoietic transplantation in the human. However, the role of NK cells in the grafted marrow or stem cells is now the focus of intensive studies. This started with a retrospective analysis of the outcome of so-called haploidentical transplantations between siblings or between parents and children, where one MHC haplotype is shared and the other not (A/B to B/C). One set of HLA-B- and -C-encoded ligands for inhibiting KIRs are thus matched, but the remaining ones may result in a combination where the graft carries an inhibitory KIR ligand that is absent from the host. The murine studies predict that this should lead to NK recognition in the graft-versus-host direction. A subgroup of transplantations representing this combination did indeed show fewer relapses of myeloid leukemia (compared with groups with complete match or KIR ligands present in the recipients but absent from the donor) (Farag et al. 2002; Ruggeri et al. 2002). Parallel studies of human NK cells in vitro or transferred to mice with human leukemia supported the role of an NK-mediated graft-versus-leukemia effect. Surprisingly, there was a reduced incidence of graft-versus-host disease in the same combinations. Experimental studies indicate that this may have been caused by efficient NK cell removal of host DCs, which initiate graft-versus-host reactivity. Follow-up studies, where the same type of mismatches occur in transplantations between unrelated individuals, have given divergent results, possibly as a result of the different recipient conditioning and graft T-cell depletion protocols involved (Davies et al. 2002; Giebel et al. 2003). The role of allogeneic, and particularly KIR-ligand-mismatched, NK cells will undoubtedly be addressed in many different clinical settings in the future, including the use of allogeneic donor lymphocyte infusions and minitransplantations for the treatment of solid tumors (Farag et al. 2002).

NK CELLS IN PREGNANCY

In immunological terms, the fetus can be regarded as an allograft. One of its HLA haplotypes is from the father, and thus foreign to the mother's immune system. The fetal–maternal interface in the decidua must provide tolerance and allow trophoblast invasion, but not beyond certain limits; defense against infections must also be provided. Cells of the NK lineage are the dominating lymphocytes in the decidua, and they may play an important role in one or several of these processes (Moffett-King 2002). The uterine NK (uNK) cells are of a particular phenotype, resembling the minor $CD56^{bright}$ subset in the blood. Their number in the endometrium starts to increase already during the post-ovulatory, secretory phase of the menstrual cycle. The uNK cells normally die as menstruation starts but, if an implantation occurs, they continue to expand and dominate the deciduas until midgestation, when placentation is complete. They then gradually disappear. The expansion of the population may be driven by IL-15 and prolactin, produced by stromal cells under the influence of the pregnancy hormone progesterone (Moffett-King et al. 2002). There are very few T cells in the decidua and no B cells.

The functional role of uNK cells is not clear. It is, however, intriguing that the MHC class I molecules expressed by the extravillous trophoblast in the decidua are HLA-E, HLA-G, and HLA-C, all of which can be recognized by different NK receptors (Moffett-King 2002). The uNK cells all express the inhibitory receptor NKG2A (recognizing HLA-E), like the $CD56^{bright}$ cells in the blood. However, the uNK cells differ from the latter in that a high proportion also expresses KIR, especially the ones recognizing HLA-C alleles. It has been proposed that inhibitory receptors prevent uNK cell lysis of trophoblast, but antibody-blocking studies in vitro do not support this. An alternate possibility is that the receptors regulate cytokine production. The uNK cells can produce the same cytokines as blood NK cells, and the invading trophoblast cells have receptors for many of these (e.g. IFN-γ, CSF1, and TNF). In addition, uNK cells produce several factors involved in angiogenesis and vascular stability. One hypothesis is that NK cells regulate trophoblast invasion and a process intimately connected to this, the transformation of maternal blood vessels in the decidua (Moffett-King 2002; Moffett-King et al. 2002). This is required for adequate fetal blood supply. Dysregulation of this process may lead to the condition preeclampsia, with risk for growth retardation of the fetus or still birth.

There are major differences in the anatomy of placentation between species, and it is therefore difficult to extrapolate observations from murine models to humans. There are some common factors and some intriguing observations from studies in mice (Croy et al. 2003). NK cells also represent the dominating lymphocyte in the mouse decidua, and they appear to be recruited from secondary lymphoid tissues during pregnancy. Mice lacking NK (and uNK) cells breed, and these cells are therefore not essential for implantation, decidualization, and completion of pregnancy. However, in the absence of uNK cells, pregnant mice show

several decidual abnormalities at midgestation, such as thick-walled decidual spiral arteries with narrow lumen diameters and a dramatic acellularity of the decidua (Moffett-King 2002; Croy et al. 2003). Studies of gene defective mice have shown that uNK cell-produced IFN-γ may be a central cytokine for vascular modifications (dilatation, elongation, and branching) of spiral arteries.

In conclusion, studies from humans and mice indicate that uNK cells play a role in regulating the trophoblast invasion and vascular transformation in the decidua. Although they are not absolutely required under normal conditions, they may be critical in pregnancies complicated by other factors.

NK CELLS IN AUTOIMMUNE DISEASES

Natural killer cell numbers and functions are often altered in patients with autoimmune disease. As in cancer and infection, such findings are not easy to interpret, because they may represent secondary alterations resulting from, for example, metabolic or other disturbances in the disease. Infiltration of autoimmune target organs by NK cells has been observed in, for example, pancreatic islets in diabetes and the synovial fluid in rheumatoid arthritis (French and Yokoyama 2004). In the latter case, all the infiltrating NK cells are of the $CD56^{bright}CD16^{low}$ cytokine-producing phenotype, which is rare in the blood. Their role in the pathogenesis of rheumatoid arthritis is unclear.

There are two rare clinical conditions where a role for 'missing self' recognition by NK cells has been proposed as responsible for autoreactivity. In the 'bare lymphocyte syndrome', there is complete lack or severely impaired MHC class I expression on cells. This can be caused by different gene defects, one of which affects the so-called TAP. When TAP expression is impaired, the HLA molecules become unstable as a result of deficient loading of peptides in the ER. A subgroup of patients with TAP deficiency suffers from necrotizing granulomatous lesions in skin and lungs, characterized by infiltration of NK cells and T cells, and leading to clinical manifestations in these organs (Zimmer et al. 1998; Moins-Teisserenc et al. 1999). There is indirect evidence that these lesions are caused by autodestructive NK cells that can recognize the 'missing self' phenotype of cells in the target tissue. There must be additional factors required for triggering of this condition, because it does not develop in all patients with the bare lymphocyte syndrome; even patient's siblings who have inherited the TAP deficiency may not develop this pattern. Most MHC class I-deficient patients thus acquire NK cell tolerance toward their own cells, just as mice with the corresponding defects. One possibility is that certain infectious agents can break this tolerance, which could explain why only certain TAP-deficient individuals are affected.

It has also been proposed that the red cell aplasia associated with benign or malignant LGL expansions may be caused by 'missing self' recognition of erythroblasts (with poor MHC class I expression) by the KIRs expressing LGLs (Lamy and Loughran 2003). Such LGL expansions may consist of T cells (αβor γδ) or NK cells, but both populations can express KIRs.

Several experimental studies have addressed the role of NK cells in animal models of autoimmunity by depleting them just before the induction or during progression of disease. Although corresponding studies in cancer, infection, and transplantation in most cases show impaired reactivity against the target or in some cases no effect, but never evidence for increased reactivity, any of the three outcomes can be observed in autoimmune models (Baxter and Smyth 2002; Flodstrom et al. 2002; French and Yokoyama 2004). There is as yet no clear-cut pattern with respect to type or localization of disease – opposite effects of NK cell depletion have even been reported in different studies of the same disease model (experimental allergic encephalomyelitis). These divergent observations are not surprising, given the complexity in the responses leading to autoimmune manifestations. The effect may thus depend on whether NK cells have a role early in induction or deviation of adaptive responses, or late as effector cells in target tissues, e.g. in a model of myasthenia gravis, NK cells promoted disease by cytokines, which skewed the response toward Th1 and production of autoantibodies to the acetylcholine receptor (Shi et al. 2000).The most consistent results have been observed in diabetes models, where NK cells in three of three cases seemed to promote disease (Flodstrom et al. 2002). The mechanisms behind this are not known, although there is evidence that NK cells can kill pancreatic β cells in vitro, suggesting a direct role as effector cells. NK cells can kill several additional normal cell types in vitro, e.g. oligodendrocytes and neurons.

In conclusion, NK cells may contribute to or prevent autoimmune disease at several levels, including cytokine-mediated stimulation, suppression or deviation of adaptive responses, and cytokine- or perforin-dependent destruction of cells in target organs. One important focus of future research is to reveal the receptors and ligands involved.

BRIEF HISTORIC INTRODUCTION

'Putrid poison', 'sepsin', and the birth of microbiology

After a long time of devastating infectious diseases, limiting the average life-time expectancy of the population worldwide until the late nineteenth century, several key findings by research pioneers in Europe not more than 120 years ago led the way to the understanding of basic principles of infection, and to the development of successful prevention and treatment strategies over the last decade. Even before the discovery of living microorganisms as the cause of infectious diseases inaugurating the discipline of microbiology, it was postulated by Panum that a 'putrid poison' was responsible for the lethal outcome of an infection (Panum 1874). Ernst von Bergmann of the Charité, Berlin in the late nineteenth century believed that a chemically defined substance was responsible for fatal infections, which he termed 'sepsin' (Bergmann and Schmiedeberg 1868).

Of course it was Louis Pasteur and Robert Koch in their ground-breaking discoveries who revealed that microorganisms are the cause of infectious diseases and they founded the new discipline of microbiology (reviewed in: Dubos 1995; Brock 1999). Although especially Koch in Berlin isolated several important bacteria presenting proof that they were the cause of disease, it still for a long time remained unclear how a given pathogen would cause a specific disease and it took a long time to define both the 'toxic' elements of microorganisms and the host's reaction patterns involved in the disease (reviewed in Beutler and Rietschel 2003).

Host–pathogen interaction as cause of many diseases of importance

Introduction of hygiene measures preventing spread of infectious diseases and the development of powerful antibiotics during the twentieth century reduced the lethality of infectious diseases in the industrial world dramatically. However, even today, certain diseases caused by microorganisms remain a clinical problem despite the highest hygiene standards and broad-spectrum antibiotics: sepsis and septic shock caused by microorganisms are still a major threat in intensive care units and statistically sepsis is a major killer in the western world (Hotchkiss and Karl 2003). Apparently, here the host reacts early to pathogens and induces a response, unfortunately not leading to limitation of the disease but to a critical state.

On the other hand, chronic inflammatory reactions account for a large number of diseases that are also particularly difficult to treat, and that lead to major

financial healthcare burdens. It is very likely that microorganisms persisting within the host account for many of these diseases, although they are not directly treatable by antibiotics (Relman 2002). Other important clinical syndromes characterized by a distinct host reaction include different forms of toxic shock syndrome, chronic parasitic diseases, or virally caused cancers, to name just a few.

Molecular mechanisms of pathogen recognition

The two reaction patterns as examples mentioned above of septic shock, on the one hand, and of chronic inflammation, on the other, depict the wide spectrum of host–pathogen interactions that can take place during an infection, and for a long time the following questions were asked:

- How is this interaction of the pathogen and the host determined?
- What molecules are involved on both sides?
- Can this reaction pattern be influenced?
- Could this be the basis for a therapy for infectious or inflammatory diseases?

Only recently, key molecular elements of the host detection system of innate immune cells were discovered with the family of Toll-like receptors (TLR), which are discussed in detail in this chapter. Furthermore, soluble molecules with the ability to detect pathogens and intracellular molecular elements of the innate immune system have been discovered, which are also outlined.

Microorganisms and their hosts – the 'battle of the genomes'

The last 120 years of microbiology since Koch have also led to the discovery of a large multitude of microorganisms displaying a wide variety of genomic organization and phenotypic appearance. Even though just a small portion of the existing microorganisms is pathogenic for humans, there is still an extremely wide variety of potentially pathogenic microorganisms. The human host, on the other hand, possesses a much larger genome compared with the microbes; however, as was revealed recently, it is smaller than expected with limited variation even between humans and other mammals. As a consequence any host organism must be overwhelmed by the task of recognizing the huge variety of potentially pathogenic microorganisms.

It has thus been postulated, and confirmed by research, lately, that the host's recognition system searches for molecular *patterns* present on distinct families of pathogens. The host apparently has sensors for these 'pathogen-associated molecular patterns (PAMP)' described in the next section and this interaction is a key step in pathogenesis of related diseases. The following section describes how the host, with the help of soluble and cellular recognition molecules, senses foreign material or dangerous situations in order to mount an appropriate response.

MICROBIAL TOXINS

Lipopolysaccharide as paradigm for pathogen-associated molecular patterns

It took several more years until the first theories on 'toxins', postulated in the pre-microbiological era by Panum and von Bergmann, were substantiated by direct evidence for the existence of a microbial substance causing the host's immune response. It was Pfeiffer who, for the first time, showed that even in the absence of live bacteria a toxic potential was present originating from bacteria and not being a protein (reviewed in Rietschel and Cavaillon 2002). This work later led to the discovery of endotoxin or lipopolysaccharide (LPS), now viewed as a classic PAMP inducing a strong activation of the innate immune system via defined molecular structures as outlined in detail below (Rietschel et al. 1996; Raetz and Whitfield 2002).

Lipopolysaccharide has a long history of excellent, thorough chemical analysis, and synthetic LPS was shown to elicit similar responses to isolated bacterial LPS in host cells. With the discovery of lipopolysaccharide-binding protein (LBP) and CD14, two of the first 'pattern-recognition receptors (PRR)' were discovered, 20 years ago, and functionally characterized in 1990 (Schumann et al. 1990; Wright et al. 1990). Further biomedical research on LPS also recently led to the discovery and functional analysis of the important PRR family of TLRs (reviewed in Beutler 2003).

A large variety of PAMPs on pathogenic microorganisms

Meanwhile, numerous pathogenic bacteria have been studied extensively, and have been analyzed chemically and genetically. Both secreted toxins, and elements of their cell walls have been well characterized and shown to bear the potential to induce innate immune responses. In addition, it has been shown that bacterial and viral nucleic acids, i.e. GC-rich oligonucleotides, can be sensed by the host's innate immune system leading to cellular activation (reviewed in Wagner 2002). These bacterial elements have furthermore been shown to be important co-stimulatory factors for inducing the adaptive immune responses, and thus are key elements as adjuvants for immunization.

MOLECULAR PATTERNS OF PATHOGENS

Are the patterns really known?

Until now it is still quite puzzling that, although certain patterns, such as LPS, present in all gram-negative bacteria, are characterized and well defined, other potentially immunostimulatory ligands of microbial source with the ability to activate immune cells are quite diverse, and seem to include such structurally distinct molecules as proteins, nucleic acids, and simple carbohydrates. Although this is still the focus of research, some molecular patterns, such as lipid structures, have been identified and are discussed at the end of this chapter.

The process of pattern recognition may also be very likely to change over time when microorganisms and the host live in symbiosis. Furthermore, selective pressure caused by antimicrobial agents may lead to rapid changes in the gene expression pattern of the pathogens and, as a consequence, to a shift in PAMP expression. Evasion and escape mechanisms of the microorganisms may lead to additional variations in patterns expressed on the surface, yet the host, in order to survive, still has to retain the ability to detect them. Novel gene array techniques may aid in analyzing this delicate balance of genetic adaptation between host and pathogen (Whitney et al. 2003). Furthermore, it has become clear that redundant pattern-recognition systems exist in order to ensure survival of the host in a changing environment.

Is pattern recognition part of the problem or part of the solution?

Despite the large success of recent research regarding both the host's and the pathogen's molecular 'arsenal', it is still not clear whether PAMPs are elements that are instrumental for the microbe to attack the host and improve survival of the pathogen, or whether the host's detection of these molecules is a key defense mechanism helping to fight off the microbes. Inflammation may be part of a successful defense reaction, and at the same time also contribute to the pathophysiology of disease. Recent results with LBP knock-out mice point in the direction that pattern recognition by the host is needed in order to combat live pathogens successfully (Jack et al. 1997; Wurfel et al. 1997; Heinrich et al. 2001; Fierer et al. 2002). Mice lacking certain PRRs were found to be unresponsive to isolated PAMPs and exhibited a worsened outcome when inoculated with whole bacteria (summarized in Werling and Jungi 2003).

Lately, studies investigating frequent single nucleotide polymorphisms (SNP) in genes encoding for TLRs in humans have been helpful for analyzing the role of these PRRs in health and disease (Lazarus et al. 2002). Analyses on the correlation of these SNPs with susceptibility to infectious diseases, discussed in detail in the final section of this chapter, are, however, controversial: although some reports show increased disease susceptibility when a PRR is genetically defective, one recent study revealed a protective effect of a TLR-4 SNP; these results were, however, obtained not for an acute infectious disease, but for an inflammatory disease, atherosclerosis (Kiechl et al. 2002).

Commensals, pathogens, and chronic inflammation

Recent research has focused on questions about the potentially beneficial role of commensal bacteria and the role of their host interaction – or lack thereof – for health and disease. Every human carries in the epigastrium more bacterial than human cells and this physiological flora clearly has important physiological functions. Why these commensals, despite carrying many of the known PAMPs, do not induce inflammatory responses is currently not known, but may be caused by a different arsenal or expression pattern of PRRs in the epigastrium (Melmed et al. 2003).

An overreaction to harmless commensals, on the other hand, has been suggested to be pathogenic in certain chronic inflammatory diseases of the gastrointestinal tract. The delicate balance between a strong defense reaction followed by the elimination of microorganisms and a 'silent symbiosis', based on the lack of early detection and interaction, most probably plays a key role in chronic inflammatory diseases in general (Kanai et al. 2002). These questions are not discussed in detail in this chapter because of a lack of space. They are closely related to topics of 'molecular mimicry' of microorganisms and the subject of autoimmune diseases, which are broadly covered in other chapters of this volume.

INNATE IMMUNITY

Adaptive and innate immunity

The discovery of the complex cellular system of the adaptive immune system during the twentieth century led to the broad application of one of the most important and successful concepts in modern medicine – immunization. The adaptive defense system, which is extensively covered in other parts of this volume, as we now know, needs repeated encounters of the host with the pathogen, and it cannot account for the rapid and potentially dramatic early reactions seen during acute infectious diseases.

In 1884, almost simultaneous with the groundbreaking discoveries of Koch and Pasteur described above, Metschnikoff discovered and described the phenomenon that certain cells within the host, which he

called 'phagocytes', are able to detect and destroy foreign structures (Metschnikoff 1844). He also recognized that phagocytes of animals immunized against *Bacillus anthracis* were able to clear bacteria faster compared with their non-immune counterparts.

With these observations, Metschnikoff founded the basic principle of innate immunity, a defense system within the host that rapidly detects foreign microorganisms, kills them, and, if necessary, evokes further adaptive mechanisms against them. Meanwhile we know that, in addition to macrophages, granulocytes and dendritic cells (DC) also contribute to this part of the immune system, as discussed in detail below.

Self, nonself, and danger

To recognize invading organisms, innate immune cells need receptors that are able to distinguish self from nonself. These receptors should be germ-line encoded in order to allow for a rapid response, i.e. within hours, in contrast to the more time-consuming processes of adaptive immunity. Furthermore, these receptors should recognize common patterns not present within the host, which are vital for the invading organisms, and therefore cannot easily be switched off. The innate immune system then activates and controls the adaptive immunity bridging these two systems (Medzhitov and Janeway 1997).

As mentioned above, these patterns are now commonly referred to as PAMPs, but it should be noted that they are expressed not only by pathogens, but also by commensals. The so-called PRRs are able to recognize a wide array of different PAMPs, including proteins, polysaccharides, glycolipids, lipids, and nucleic acid, as discussed below. Notably, some PRRs also detect endogenous ligands. These findings may be explained by the recently proposed 'danger model' (Matzinger 2002), which, in contrast to the 'self–nonself' model explained before, states that PRRs not only recognize structures of invading organisms, but also recognize molecules associated with dangerous circumstances in common, including, for example, breakdown products of necrotic cells (Figure 1). Recent studies confirm this hypothesis by showing that only structures released by necrotic (or 'attacked') cells, but not apoptotic (or 'selfinduced death') cells, share this feature (Sauter et al. 2000).

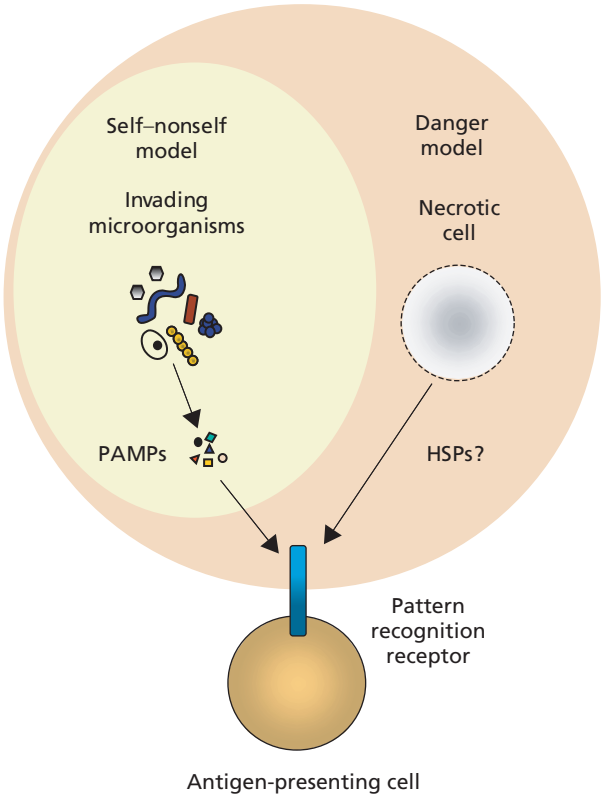

Figure 1 *General principles of pattern recognition by antigen-presenting cells (APC). APCs such as macrophages or dendritic cells (DC) play a key role in early innate immunity. They recognize molecular patterns associated with infection or danger via pattern recognition receptors (PRR). According to the self–nonself model, PRRs exclusively recognize pathogen-associated molecular patterns (PAMP), followed by the initiation of immune responses. The proposed danger model suggests that, in addition to PAMPs, endogenous molecular patterns associated with infection or trauma, e.g. partial structures of necrotic cells or released heat shock proteins (HSP), bind to PRRs, initiating an immune response.*

CELLS OF THE INNATE IMMUNE SYSTEM

Antigen-presenting cells

Cells participating in innate immune recognition share the ability of detecting invading microorganisms via PRRs, followed by phagocytosis and digestion. Next, partial structures are shuttled to the outside of the cell in order to present them to other immune cells via major histocompatibility complex (MHC) class I and II molecules (Thery and Amigorena 2001). The complex process of antigen presentation is described in detail in other chapters of this volume. Immune cells sharing this feature are commonly referred to as antigen-presenting cells (APC).

Antigen-presenting cells include granulocytes, monocytes, and macrophages, as well as DCs (Underhill et al. 1999a). As a result of their capacity to present antigen and thus to orchestrate the induction of the adaptive immune response, DCs are currently studied extensively in almost all fields of immunology, including tumor immunology (Banchereau and Steinman 1998). To give an overview of these cells centrally involved in pattern recognition and innate immunity, Figure 2 shows how hemopoietic stem cells differentiate early on into common myeloid progenitor cells (CMP) and common lymphoid progenitor cells (CLP).

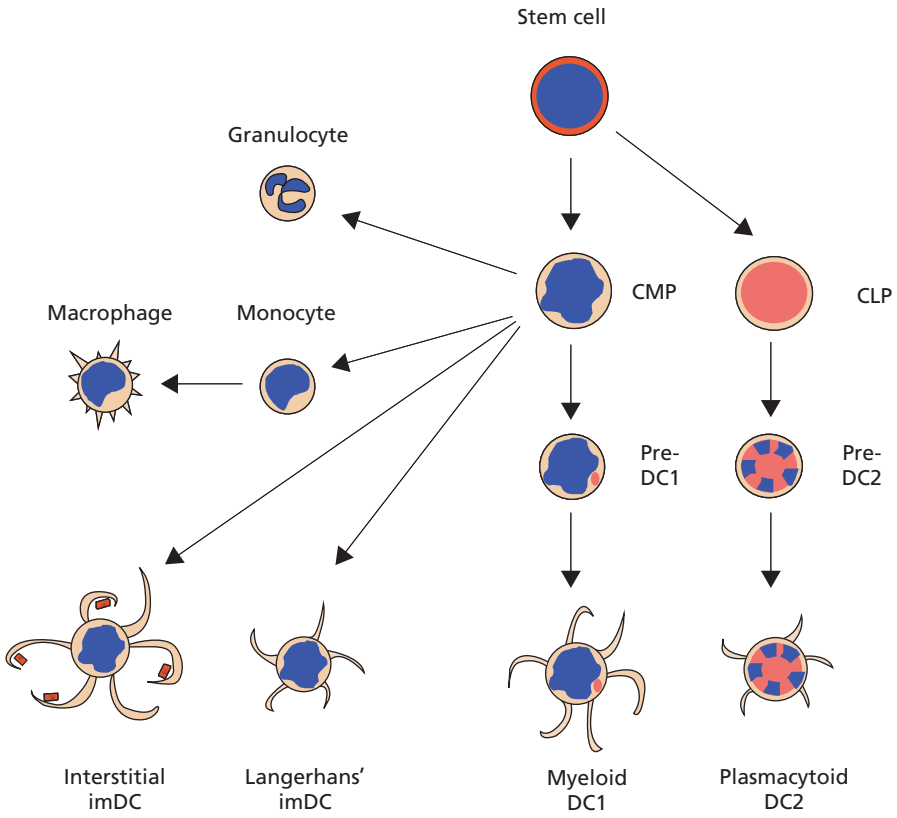

Figure 2 *Overview on the hemopoiesis of antigen-presenting cells. Hemopoietic stem cells differentiate into common myeloid progenitor cells (CMP) and common lymphoid progenitor cells (CLP). CMPs give rise to granulocytes and monocytes, which are able to differentiate into tissue macrophages. CMPs can also differentiate into immature dendritic cells (imDC). The imDCs found in the skin are referred to as Langerhans' imDCs, whereas those migrating to the dermis and other tissues are called interstitial imDCs. These are, in contrast to the Langerhans' cells, capable of large-scale phagocytosis and produce interleukin 10 (IL-10), leading to activation of T and B lymphocytes. CMPs are furthermore progenitors of the so-called premature myeloid or DC type 1 cells (pre-DC1), which, similar to their immature interstitial counterparts, are capable of phagocytosis. Premature plasmacytoid or DC type 2 (pre-DC2) cells, in contrast, are unable to phagocytose microorganisms; instead they are producers of the type 1 interferons, i.e. interferon-α and -β.*

Hemopoiesis of dendritic cells

Different classes of DCs have been described and are found in specific tissues of the host: CMPs differentiate into granulocytes, monocytes, and $CD34^+$ late progenitor cells. The last include two subsets: CLA^+ and CLA^- cells. CLA^+ cells differentiate into $CD11c^+CD1a^+$ Langerhans' cell precursors, which migrate into the skin and develop into Langerhans' immature DCs (imDC). CLA^- cells differentiate into $CD11c^+CD1a^-$ interstitial DC precursors, which travel to the dermis, becoming interstitial dendtritic cells. This subset of imDCs is capable of ingesting large quantities of microbial material and initiating IgM production by B cells. CMPs also differentiate into pre-DCs type 1 or monocytic pre-DCs, whereas CLPs differentiate into pre-DCs type 2 or plasmacytoid DCs. Pre-DCs type 1 express antigens related to monocytes, including CD14, CD11, CD13, and CD33 (Liu et al. 2001), whereas pre-DCs type 2 bear markers related to lymphocytes, such as pre-T-antigen and Spi-B (Spits et al. 2000; Bendriss-Vermare et al. 2001). In general, pre-DCs type 1 are capable of phagocytosis of microorganisms, whereas pre-DCs type 2 synthesize large amounts of class 1 interferons, with implications for immune responses to viral infections, as discussed in detail below (Kadowaki and Liu 2002).

PATTERN RECOGNITION RECEPTORS

Basic characteristics

A growing number of PRRs have been identified and are summarized in Table 1. Generally two classes can be distinguished: one binds microbial structures leading to detoxification and inhibition of cellular responses. The other group is involved in the induction of signal transduction and the stimulation of responses of the innate immune system. Cellular PRRs are generally found within the membrane of any host cell; however, they are predominantly found in APCs. Furthermore, intracellular forms of PRRs have been described with the function of binding microbial structures after phagocytosis of microorganisms. Finally, soluble PRRs, with

Table 1 *Overview on pattern recognition receptors*

Receptor	Origin	Ligands	Function
Cell surface			
Type 3 complement receptor	Monocytes/macrophages	Complement opsonized particles	Phagocytosis
Scavenger receptors	Macrophages	Anionic polymers	Clearance/phagocytosis
C-type lectins	Macrophages	Carbohydrates with mannose residues	Phagocytosis
CD14	Monocytes/macrophages	LPS, LTA, lipoproteins, peptidoglycan	Cytokine induction
Toll-like receptors	Various, including monocytes/ macrophages, dendritic cells, endothelia	Various, including compounds derived from bacteria, virus, fungi, and protozoa	Cytokine induction
Intracellular			
BPI	Neutrophilic granulocytes	LPS	Killing of engulfed gram-negative bacteria
nod1/nod2	Various, including monocytes/ macrophages and epithelia	Peptidoglycan	Innate immune responses
Soluble			
LPS-binding protein	Acute phase protein synthesized in the liver	LPS, LTA	Cytokine induction
CRP	Acute phase protein synthesized in the liver	Phosphorylcholine	Activation of the classic complement pathway
Soluble CD14	Monocytes/macrophages	LPS, LTA, lipoproteins Peptidoglycan	Cytokine induction

According to Medzhitov et al. (1997), PRRs can be classified regarding their distribution in cell-surface, intracellular and soluble PRRs. This table gives an overview on some PRRs, their origin and their function. Note that, in some cases, origin and function are currently still the subject of controversial discussion.
BPI, bactericidal/permeability increasing protein; CRP, C-reactive protein; LBP, LPS-binding protein; LPS, lipopolysaccharide; LTA, lipoteichoic acid.

the function of binding and presenting the microbial target to cellular receptor or enabling phagocytosis (opsonic function), have also been described. A common feature of all PRRs is that they recognize common structures of invading microorganisms, followed by the initiation of immune responses. PRRs can be distinguished into cell-surface, intracellular, and secreted PRRs (Medzhitov 2001) (Table 1).

Cell-surface PRRs

Besides the TLR family, which is discussed in detail later, other cellular receptors for microbial ligands have been described, and three examples are given here. A membrane-bound PRR is the type 3 complement receptor, a β_2-integrin also known as CD18/CD11b. It is present on macrophages, enabling phagocytosis of complement-opsonized particles or whole pathogens (Ross 2000). CD18/CD11b has been proposed as being involved in LPS-mediated signal transduction in cooperation with CD14; however, these results are still not conclusive (Flo et al. 2000). Furthermore, the large family of scavenger receptors is expressed not only by macrophages but also by certain endothelial cells. They bind to a wide array of polyanionic ligands, including exogenous molecules such as LPS of gram-negative bacteria or endogenous compounds, i.e. low-density lipoprotein (LDL) (Krieger and Stern 2001). Interaction of bacterial ligands with members of the scavenger receptor family does not induce signal transduction, but leads to detoxification of the ligands.

Another group of cell surface PRRs is the C-type lectins, including mannose receptors and denditric cell-specific ICAM-grabbing nonintegrin (DC-SIGN). Mannose receptors are expressed by macrophages, DCs, and some endothelial cells, whereas DC-SIGN is restricted to DCs (Geijtenbeek et al. 2002). They bind mannosyl/fucosyl as well as glucosamine residues (East and Isacke 2002), which are commonly found on the bacterial surface. The interaction of mannose receptors with pathogens, affecting intracellular signaling, is not fully elucidated by now, however, there is evidence that virulent strains of *Mycobacterium tuberculosis* are phagocytosed via a pathway involving mannose receptors, whereas their avirulent counterparts are not (Kang and Schlesinger 1998).

Intracellular PRRs

BACTERICIDAL/PERMEABILITY INCREASING PROTEIN

Bactericidal/permeability-increasing protein (BPI) is a predominantly intracellular protein with the ability to bind LPS with high affinity (Weiss et al. 1978). It can

therefore be referred to as an intracellular PRR. BPI is found within the primary granules of polymorphonuclear neutrophils (PMN), has bactericidal properties toward gram-negative bacteria, and apparently binds whole bacteria or LPS within the phagocytic compartment of the cell in order to kill engulfed bacteria. BPI is one of the first PRRs that entered clinical trials (Neuprex) in order to modulate the innate immune response brought about by LPS during sepsis, which is discussed in the final chapters (Elsbach and Weiss 1998).

Recently, intracellular PRRs termed 'NOD1' and 'NOD2' were described with the ability to participate in the induction of programmed cell death. It has been suggested that NODs, which share structural similarity with TLRs, are involved in intracellular recognition of LPS and other bacterial partial structures; however, these results still have to be confirmed (Inohara and Nunez 2001). The next section covers some of the results from basic science on NOD2 and the final section of this chapter summarizes the findings of the relationship between NOD2 polymorphisms and Crohn's disease. TLR-9 is another intracellular PRR that recognizes bacterial DNA, which is discussed separately later under Recognition of bacterial DNA by TLR-9.

PRR ROLE FOR NOD2/CARD 15?

A member of a recently discovered, growing family of proteins containing a so-called caspase-recruitment domain (CARD) involved in apoptosis regulation, originally termed 'nucleotide-binding oligomerization domain (NOD)', has recently been postulated to recognize LPS and bacterial muramyldipeptide (MDP) intracellularly (Girardin et al. 2003; Inohara et al. 2003). NOD proteins are related to the family of membrane-bound R-proteins of plants involved in plant host defense (Dangl and Jones 2001). Several NOD proteins in humans have been identified and NOD1 (also called CARD 4) has been implicated with LPS recognition, whereas NOD2 (also called CARD 15), although previously suggested also to recognize LPS, has recently been shown to be involved in MDP recognition (Inohara and Nunez 2001; Inohara et al. 2003).

The NOD proteins all contain leucin-rich repeat (LRR) domains and share homology with the apoptosis regulator apoptotic protease-activating factor-1 (Apaf-1) (Bertin et al. 1999). NOD2/CARD 15 is expressed only by monocytes and recently has gained attention because of a correlation of SNPs with the incidence of Crohn's disease and a rare disease called Blau syndrome (arthritis, uveitis, and skin rash) in humans (see details later under The NOD2/*CARD15* SNPs). A frameshift mutation here leads to a truncated protein that is apparently unable to respond to LPS or MDP (Ogura et al. 2001b; Girardin et al. 2003; Inohara et al. 2003).

The CARD-containing proteins and certain TLRs signal via a CARD-containing serine/threonine kinase termed 'RICK/Rip2/CARDIAK', leading to NF-κB translocation (Kobayashi et al. 2002). The family of CARD/NOD proteins, in summary, are related to TLRs and CD14 with regard to their structure of LRRs, and may serve as intracellular sensors for PAMPs.

Soluble PRRs

SOLUBLE CD14

CD14 is a PRR present on monocytes, macrophages, granulocytes, and DCs, attached to the cell via a phosphatidylinositol (PI) anchor that is unable to transduce signals into the cell (Goyert et al. 1988; Pugin et al. 1994). Cellular CD14 has been shown to be part of a lipid raft allowing for clustering of several PRRs upon ligand stimulation (Pfeiffer et al. 2001). This may serve the function of concentrating bacterial ligands locally in order to be presented to a signal-transducing receptor such as members of the TLR family (Schmitz and Orso 2002).

A second, slightly smaller, form of CD14 termed 'soluble CD14' (sCD14) is released into serum, and both forms play a crucial role in pattern recognition (Schumann and Latz 2000). CD14 has been shown to bind to LPS, a glycolipid present in the outer membranes of gram-negative bacteria (Wright et al. 1990; Rietschel et al. 1996; Alexander and Rietschel 2001). CD14 is also involved in recognition of other bacteria and in initiation of phagocytosis. It leads to an accumulation of PAMPs, enabling recognition by the signal-transducing molecules of the TLR family (Schumann et al. 1994; Landmann et al. 2000). CD14 contains LRRs, a structural characteristic typical of many PRRs including the TLRs addressed in detail below under The family of Toll-like receptors (Ziegler-Heitbrock and Ulevitch 1993).

LIPOPOLYSACCHARIDE-BINDING PROTEIN

During cell growth and death, gram-negative microorganisms release LPS (Brandtzaeg et al. 1989), and in serum it is primarily recognized and bound by LPS-binding protein (LBP), (Figure 3), another soluble PRR. LBP is mainly synthesized in the liver, catalyzing the transfer of LPS to CD14 (Schumann et al. 1990) and enabling the cells to respond with, for example, cytokine release (Figure 3 and Table 1) (Alexander and Rietschel 2001). LBP is a typical acute phase protein that is induced upon stimulation during the acute phase response via interleukin 1 (IL-1), IL-6, and dexamethasone (Schumann et al. 1996). It belongs to a family of proteins that share the ability to bind lipid-like structures including another LBP called BPI, cholesterol ester-transfer protein (CETP), and phospholipid-transfer protein (PLTP) (Kirschning et al. 1997).

Epithelial cells both of intestinal origin and from the respiratory tract have been found to be sources of LBP as well (Vreugdenhil et al. 1999; Dentener et al. 2000). Both CD14 and LBP have been found to be involved in

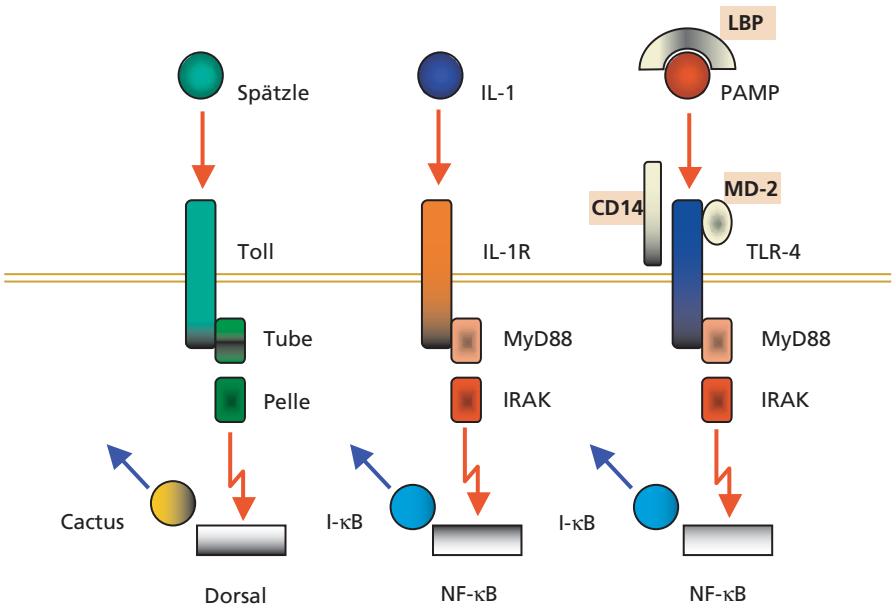

Figure 3 *Comparison of signal transduction via drosophila Toll-like receptors (TLR), interleukin 1 receptor (IL-1R), and TLR-4. In* Drosophila*, signal transduction via Toll is initiated by the cleavage of the endogenous ligand* spätzle*, which binds to Toll, initiating a signal transduction cascade involving the adapter molecule* tube *and the kinase* pelle*. After the inhibitory factor* cactus *has dissociated, the transcription factor dorsal translocates into the nucleus, initiating certain transcriptional events. This pathway – because of the sequence homologies – shares striking similarities with the known IL-1R, as well as with the recently identified TLR-4 signaling pathway (almost similar among all other members of the TLR family). After the receptor has recognized its ligand (IL-1 or lipopolysaccharide (LPS)), signaling in both cases involves the adapter molecule MyD88 and the kinase IRAK. The inhibitory factor IF-κB dissociates and the transcription factor NF-κB translocates to the nucleus inducing immune responses. An equivalent of the protease cascade, leading to release of the endogenous ligand* spätzle *in the IL-1/TLR pathway has not yet been found. Instead, for recognition of LPS, several soluble pattern recognition receptors (PRR) are involved with LPS-binding protein (LBP), transferring LPS to the receptor complex, which in addition to TLR-4 also involves CD14 and MD-2.*

recognition of other bacterial structures, such as spirochetal glycolipids, pneumococcal peptidoglycan, lipoteichoic acid (LTA), and others (Perera et al. 1997; Kurt-Jones et al. 2000; Schroder et al. 2000, 2003).

Recently LBP was found to serve a dual role during infection, depending on the local concentration in relation to the concentration of the bacterial ligand. Although small concentrations of LBP enable host cell responses to LPS, high concentrations of LBP, as present in human serum, inhibited cellular LPS-induced signaling (Lamping et al. 1998; Hamann et al. 2000; Zweigner et al. 2001). The soluble PRR LBP may serve both of the functions of innate immunity mentioned above. Early detection of pathogens and induction of the immune response, and fighting off the bacteria and inhibiting its host effects, depend on its concentration, which is tightly regulated during the acute phase.

THE FAMILY OF TOLL-LIKE RECEPTORS

General characteristics of TLRs

BASIC LESSONS LEARNED FROM FLIES

Drosophila Toll was discovered in the early 1980s during a mutagenesis screen by Anderson and Nüsslein-Vollhard (1984). It was further characterized as a factor crucial for dorsoventral axis formation within the drosophila embryo and includes a total of 12 genes (Hashimoto et al. 1988). It is said that the German researcher and Nobel laureate Christine Nüsslein-Volhard, after discovery of this factor, spontaneously shouted 'Toll!', which in German means 'great!'. Toll activation in *Drosophila* also involves a ligand termed *spätzle*, the adaptor protein *tube*, the protein kinase *pelle*, as well as the transcription factor *dorsal* and its inhibitor *cactus* (Medzhitov and Janeway 1998) (see Figure 3).

In the late 1990s it was found that there are striking sequence similarities between all members of this pathway and the mammalian interleukin 1 receptor (IL-1R) signal transduction pathway (Medzhitov et al. 1997). It was postulated that *toll* may also play a role in the innate immunity of *Drosophila*. This was supported by the finding that fruit flies deficient of members of this pathway are highly susceptible to fungal infections, however, immunity against bacteria is not impaired (Lemaitre et al. 1996). Another member of the *toll* family, 18-wheeler, is apparently involved in bacterial recognition (Williams et al. 1997), although the signaling pathways involved are different from *toll* (Medzhitov 2001). A further demonstration of an immune function of *toll* relates to its involvement in the induction of antimicrobial peptides, i.e. Drosomycin and Metchnikowin (reviewed in Imler and Hoffmann 2002, 2003).

FIRST EVIDENCE FOR THE ROLE OF TLRS IN MAMMALS

The previous results, and the fact that IL-1 stimulation of human cells leads to similar effects as compared with stimulation with bacterial ligands, led to studies investigating the potential role of mammalian homologs of *toll*, also called 'Toll-like receptors' in innate immunity (Rock et al. 1998). First reports concluded that human TLR-2 was involved in LPS-mediated signaling (Kirschning et al. 1998; Yang et al. 1998). Later it was found that these studies may have been performed in the presence of lipoproteins, structures now known to be classic TLR-2 agonists. Extensive positional cloning studies that analyzed LPS-hyporesponsive C3H/HeJ mice and the formerly termed LPS gene, leading to hyporesponsiveness to LPS, led to the finding that these mice carried a mutation in the gene encoding for TLR-4. These studies and the development of the TLR-4 knockout mouse revealed that TLR-4 was the long-sought-after LPS gene responsible for detection of LPS (Poltorak et al. 1998; Beutler et al. 2001). It is now agreed that TLR-2 recognizes a wide variety of other bacterial ligands, mainly of gram-positive pathogens (see below under Ligands of the heterodimeric TLR-2–TLR-1–TLR-6 complex, and Table 2) and some rare and atypical forms of LPS.

STRUCTURE OF TLRs

All TLRs described by now are type I transmembrane receptors characterized by the presence of LRRs within the extracellular domain (O'Neill and Dinarello 2000). The role of LRRs in TLR function is currently not completely elucidated. However, proteins exhibiting LRRs, e.g. ribonuclease inhibitors (Kobe and Deisenhofer 1995), have been shown to exhibit a 'horseshoe-like' structure (Figure 4), with the LRRs being relevant for interaction with a proteinaceous ligand. It should be noted that other PRRs besides the TLRs, such as CD14, the NODs, and RP105, share the LRR architecture (Kirschning and Schumann 2002). It is thus tempting to speculate that this structural feature is involved in pattern recognition brought about by these proteins.

Toll-like receptors all possess an intracellular signaling region exhibiting homologies to IL-1R, also referred to as Toll/IL-1R receptor (TIR) domain (see Figure 3). There are a total of 20 proteins with TIR domains so far identified in the human genome, and many TIR-domain-containing proteins have been described in other species including plants (O'Neill 2002). The structure of the TIR domain of TLR-1 and -2 has recently been solved; it contains a crucial region for signaling, as the mutation of the LPS-unresponsive HeJ mouse is located in this region (Xu et al. 2000). Signal transduction events initiated by TLR–ligand interaction are discussed in detail later under Signal transduction cascade induced by TLR-ligand interaction. It may be noteworthy that RP105, a receptor associated with MD-1 and also containing LRRs, lacks a TIR domain. Apparently, most of the TLRs described form heterodimers in order to induce signaling, TLR-4 most probably forming homodimers.

Table 2 *Toll-like receptors and their agonists: an overview*

Receptor	Ligand
TLR-1	Diacylated lipoproteins/lipopeptides (TLR-1/2 heterodimers)
TLR-2	Lipoproteins/lipopeptides (various)
	Peptidoglycan (gram-positive bacteria)
	Lipoteichoic acid (gram-positive bacteria)
	Lipoarabinomannan (mycobacteria)
	Spirochetal glycolipids (*Treponema* spp.)
	Zymosan (crude candida particles)
	Atypical lipopolysaccharide (LPS) (*Leptospira interrogans*)
	Atypical LPS (*Porphyromonas gingivalis*)[a]
	Glycoinositolphospholipids (*Trypanosoma cruzi*)
	Neisseria porins
	Heat shock protein (HSP) 70 (host)
TLR-3	Double-stranded RNA
TLR-4	LPS (gram-negative bacteria)[b]
	Respiratory syncytial virus fusion protein
	HSP 60 (*Chlamydia* spp.)
	β-Defensins (host)
	HSP 60 (host)
	HSP 70 (host)[c]
TLR-5	Bacterial flagellin
TLR-6	Triacylated lipoproteins/lipopeptides (TLR-1/6/ heterodimers)
TLR-7	Imidazoquinolines (antiviral compounds)
	Loxoribine (antiviral compounds)
	Single-stranded V-rich RNA (in mice)
TLR-8	See TLR-7
TLR-9	CpG DNA
TLR-11	Uropathogenic *E. coli* (in mice)

Ligands are ordered according to the different members of the TLR family. Note that some reports have been questioned.
a) Synthetic LPS of *P. gingivalis* has been reported to act as a TLR-4 ligand.
b) According to some investigators, LPS is the sole ligand for TLR-4.
c) Human HSP 70 has been reported to be devoid of stimulating capacities in the absence of contaminating LPS.

TLR TISSUE DISTRIBUTION

Toll-like receptors are not equally distributed among APCs, with monocytes as well as monocytoid or type 1 DCs expressing a rather wide variety of TLRs, whereas plasmacytoid or type 2 DCs preferentially express TLR-7 and TLR-9 (Kadowaki et al. 2001) (Table 2). Other cells types not exclusively contributing to innate immunity have also been described as expressing different TLRs, e.g. endothelial cells predominantly exhibit TLR-4, whereas TLR-2 is usually weakly expressed (Faure et al. 2000), a pattern that is also found in intestinal epithelial cells (Melmed et al. 2003). TLR-3 expression appears to be restricted to DCs, whereas TLR-9 is

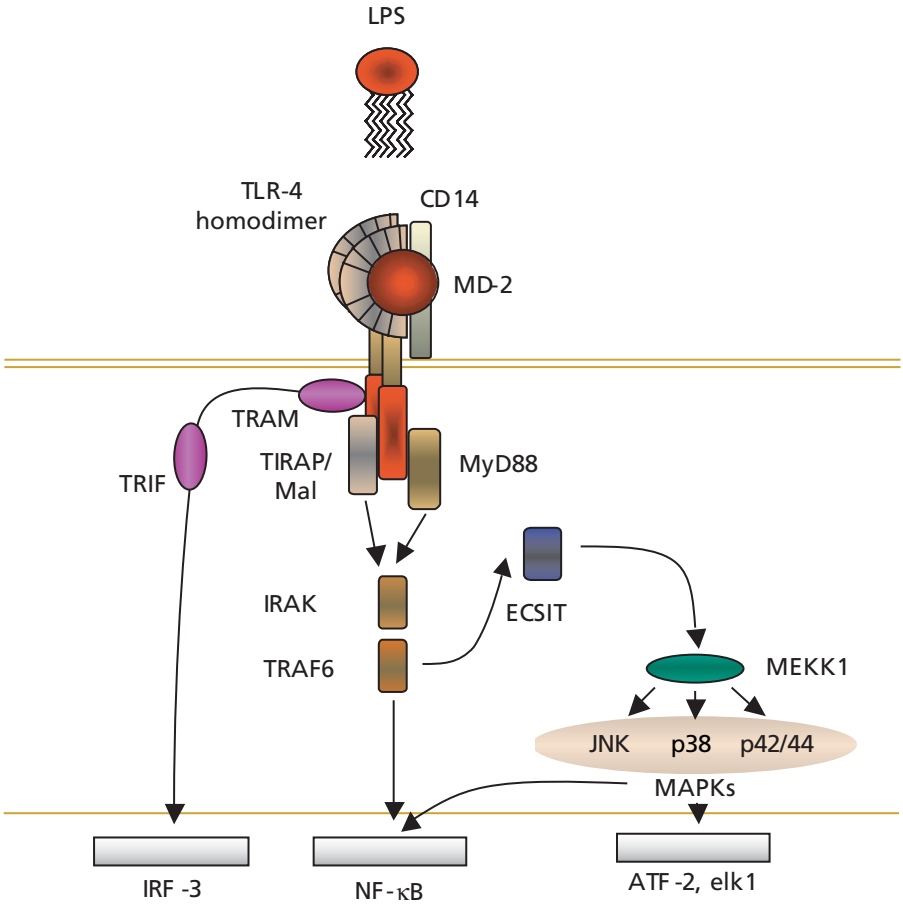

Figure 4 *Signaling pathways of Toll-like receptor 4 (TLR-4). Lipopolysaccharide (LPS) interacts with its receptor complex consisting of CD14, MD-2, and a TLR-4 homodimer or multimer. There are several pathways leading to signal transduction into the nucleus, which are discussed in detail later under Signal transduction cascade induced by TLR-ligand interaction. The MyD88-dependent pathway, in addition to MyD88, involves IRAK, TRAF-6, and the transcription factor NF-κB. TRAF6 also interacts with ECSIT, in turn leading to activation of MAP/erk kinase kinase (MEKK1) and subsequently several MAPKs, involving p38, p42/44, and JNK. Diacylated amphiphilic ligands, such as MALP-2 or lipotechoic acid (LTA) interacting with TLR-2/TLR-6 heterodimers, have been shown to activate several other transcription factors, including ATF-2 and elk1. There are at least two MyD88-independent signal transduction pathways: One involves TIRAP/Mal, which activates IRAK and the other downstream elements known from the MyD88-dependent pathway. Furthermore, activation of the TLR-4 receptor complex via recently identified signaling elements TRAM and TRIF leads to activation of Interferon regulatory factor 3 (IRF-3).*

detectable predominantly on B cells and, as mentioned above, type 2 DCs (Muzio et al. 2000). TLR-2 has been shown to be expressed, or upregulated, within the brain (Koedel et al. 2003). The following sections discuss the characteristics of particular TLR subfamilies in detail; a general overview on the agonists found for the given TLRs is given in Table 3.

TLR-1, TLR-2, TLR-6, and TLR-10

LIGANDS OF THE HETERODIMERIC TLR-2–TLR-1–TLR-6 COMPLEX

Toll-like receptor 2 was the first member of the TLR family shown to be involved in pattern recognition (Kirschning et al. 1998). Over the last few years TLR-2 has been found to be involved in recognition of microorganisms of almost all types including, for example, peptidoglycan and LTA of gram-positive bacteria (Schwandner et al. 1999; Opitz et al. 2001), bacterial lipopeptides of *Borrelia* and *Mycoplasma* spp. (Lien et al. 1999), lipoarabinomannan of mycobacteria (Means et al. 1999), and zymosan of *Candida* spp. (Underhill et al. 1999b) (reviewed in Kirschning and Schumann 2002). TLR-2 apparently does not interact with MD-2 but, as CD14 has been shown to play a crucial role in cytokine induction by LTA, peptidoglycan, and lipopeptides (Weidemann et al. 1997; Sellati et al. 1998; Hermann et al. 2002), it is very likely that CD14 is also part of the TLR-2 receptor complex. TLR-2, next to its cell surface expression, also appears intracellularly, but only after phagocytic processes (Underhill et al. 1999b).

The high degree of homology among TLR-2, TLR-1, and TLR-6 corresponds to the fact that these receptors are able to form heterodimers (Ozinsky et al. 2000). Apparently, LTA and mycoplasma lipopeptide

Table 3 *Ligands of Toll-like receptors classified according to their origins*

Organism	Substance class	Ligand	Receptor
Bacteria	Glycolipid	LPS (gram-negative)	TLR-4
		LPS *L. interrogans*	TLR-2
		LTA (gram-positive) lipoarabinomannan (mycobacteria)	TLR-2
		Spirochetal glycolipids (*Treponema* spp.)	TLR-2
	Lipoprotein/lipopeptide	Lipoprotein (*Borrelia burgdorferi*)	TLR-2/-1
		Mycoplasma spp. (lipopeptide)	TLR-2/-6
	Nucleic acid	CpG	TLR-9
	Protein	Flagellin	TLR-5
		Neisseria porins	TLR-4
		Chlamydia HSP	TLR-2
	?	Uropathogenic *E. coli*	TLR-11
Fungi	Various	Zymosan	TLR-2
Protozoa	Glycolipids	Glycoinositolphospholipids	TLR-2
Virus	Nucleic acid	Double-stranded RNA	TLR-3
		Single-stranded RNA	TLR-7/-8
	Protein	RSV fusion protein	TLR-4
Endogenous	Saccharides	Hyaluronic acid oligomers	TLR-4
		Heparan sulfate	TLR-4
	Proteins	HSP 60 and 70	TLR-4
		HSP 70	TLR-2
		β-Defensins	TLR-4
Others		Paclitaxel	TLR-4
		Antiviral compounds	TLR-7/-8

TLR ligands are classified according to their origin. Ligands derived from bacteria, viruses, fungi, and parasites are listed. Note that there are also reports on endogenous ligands of TLRs derived from the host, not listed here.
HSP, heat shock protein; LPS, lipopolysaccharide; LTA, lipoteichoic acid; RSV, respiratory syncytial virus.

(MALP-2) are recognized by dimers consisting of TLR-2 and TLR-6 (Morr et al. 2002; Takeuchi et al. 2001), whereas borrelia lipoproteins and their synthetic lipopeptide counterparts, respectively, interact with TLR-2/TLR-1 dimers (Takeuchi et al. 2002). Taken together, these data indicate that diacylated amphiphilic molecules (i.e. MALP and LTA) in common are recognized by TLR-2/TLR-6, whereas triacylated molecules (i.e. borrelia lipoproteins) are recognized by TLR-2/TLR-1 (Figure 5). Until now, however, no ligand has been described for TLR-10. As this putative receptor exhibits high homology to TLR-1 and TLR-6, it is tempting to speculate that it also forms heterodimers with TLR-2.

IS THERE STILL EVIDENCE FOR TLR-2 BEING AN LPS RECEPTOR?

There have been several reports on 'atypical' LPS molecules interacting with TLR-2 and not with TLR-4. These reports mainly focused on the LPS of *Leptospira interrogans* and *Porphyromonas gingivalis* (Hirschfeld et al. 2001; Werts et al. 2001). In this context, the term 'atypical' describes a lipid A portion of LPS being less phosphorylated and lacking secondary fatty acids compared with the well-characterized Enterobacteriaceae lipid A. However, *Porphyromonas gingivalis* LPS has been described to act as a sole TLR-4 agonist after extensive purification, and synthetic preparations of its lipid A also do not display any interaction with TLR-2 (Ogawa et al. 2002).

Toll-like receptor 3

Toll-like receptor 3 has been shown to recognize double-stranded RNA (dsRNA), which is found during viral infections (Alexopoulou et al. 2001). This evidence was obtained by transfection of a TLR-3-negative cell line, rendering it responsive to dsRNA, as well as studies on TLR-3-deficient mice, which were more susceptible to administered dsRNA in comparison to their wild-type counterparts.

Signal transduction involves MyD88 and NF-κB, or the MyD88-independent TICAM-1 pathway (see later under Signal transduction cascade induced by TLR-ligand interaction). Double-stranded RNA, or its synthetic counterpart, polyinosinic–polycytidylic acid [poly(I):poly(C)] (Alexopoulou et al. 2001) is known to be a potent inducer of type I interferons, such as interferon-α (IFN-α) and IFN-β, which are mainly synthesized by plasmacytoid DCs. However, these cells do not express TLR-3 (Kadowaki et al. 2001). Thus, dsRNA may in addition interact with other receptors. Furthermore, TLR-3, predominantly expressed in monocytoid DCs, may also bind other as yet unidentified ligands. TLR-3 stimulation has recently been

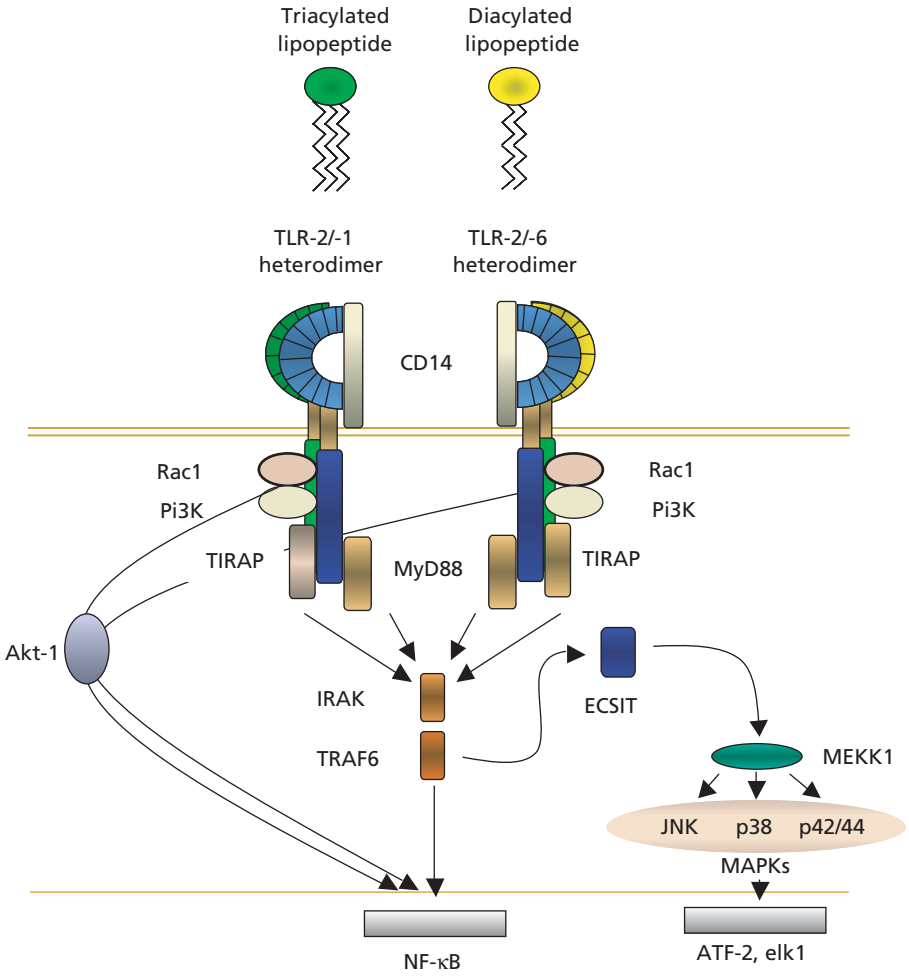

Figure 5 *Toll-like receptor 2 (TLR-2)-associated signaling pathways. The TLR-2 receptor complex consists of a heterodimer and apparently involves CD14, as well as TLR-1 or TLR-6. Triacylated amphiphilic molecules, i.e. lipopeptides based on the lipoprotein basic structure of* Borrelia burgdorferi *lipoproteins, interact with TLR-2/TLR-1 heterodimers, whereas diacylated amphiphilic ligands, such as MALP-2 or lipoteichoic acid (LTA), interact with TLR-2/TLR-6 heterodimers. Signal transduction involves the MyD88-dependent pathway or the TIRAP/Mal pathway, largely MyD88 independent (see Figure 4). Furthermore, NF-κB translocation is brought about by a signaling cascade involving phosphatidylinositol 3 (PI-3) kinase and Rac1, forming a complex with TLR-2, and AKT. Note that this pathway has also been demonstrated for TLR-4.*

found to induce a complex set of antiviral responses, which are more efficient in fighting viruses compared with stimulation of TLR-4 (Doyle et al. 2003).

Toll-like receptor 4

THE LPS RECEPTOR

With the exception of the LPS–TLR-2 interaction mentioned above, TLR-4 is currently viewed as the sole receptor for bacterial LPS (Beutler et al. 2001). The term 'receptor' appears premature because LPS binding to TLR-4 has not been shown yet; however, binding of LPS to MD-2, a TLR-4 adaptor protein, could be demonstrated (Viriyakosol et al. 2001). It is most likely that TLR-4 forms homodimers or multimers and this receptor complex also involves CD14 and the adaptor molecule MD-2 (da Silva Correia et al. 2001).

Despite the previous finding that TLR-2 is involved in LPS recognition, numerous studies have provided evidence that TLR-4 is the main cellular 'receptor' for LPS (Chow et al. 1999; Heine et al. 1999). TLR-4, therefore, has been found to contain the ability to discriminate LPS types differing in their lipid content within their lipid A moiety, leading to divergent levels of activity (Lien et al. 2000). Transfection of TLR-4 from different species was able to transfer the ability of certain types of LPS to act as active agonist, inactive non-competitive molecule, or antagonist (Poltorak et al. 2000). It has also been shown, by laser scanning microscopy, that the CD14–TLR-4–MD-2 complex specifically travels within the cell to and from the Golgi apparatus transporting LPS, a process that is, however, separate from the induction of signal transduction (Latz et al. 2002).

The crucial role of MD-2 for LPS recognition by TLR-4 could be demonstrated by transfection experiments

(Shimazu et al. 1999), as well as by studies employing MD-2-mutant cell lines (Schromm et al. 2001). Recently, the generation of MD-2-deficient mice clearly showed that MD-2 is absolutely essential for host LPS recognition (Nagai et al. 2002). MD-2 has been shown to form dimers; however, the monomeric form seems to be important for LPS recognition (Re and Strominger 2002). The principle of TLR-4 and MD-2 forming a receptor complex exhibits striking similarities with RP105, the LRR-containing receptor present on B lymphocytes that is associated with an MD-2-related adaptor protein called MD-1 (Miyake and Shimazu 1998). RP105, however, is the only LRR-containing molecule lacking the TIR domain described later, which has been found to be essential for signaling (Miyake 2003).

NON-LPS LIGANDS OF TLR-4

Following the finding that LPS is an agonist for TLR-4, other potential ligands have been proposed to interact with the TLR-4 receptor complex, which are, apart from paclitaxel (Kawasaki et al. 2000), proteins. These include bacterial chlamydia heat shock proteins (HSP) (Costa et al. 2002), viral respiratory syncytial virus (RSV) fusion protein (Kurt-Jones et al. 2000), as well as endogenous compounds, especially host HSPs (Ohashi et al. 2000) (summarized in Table 3). It should be noted that studies of interactions of TLR-4 with proteins expressed in gram-negative bacteria, such as *E. coli*, are often hampered by contaminating LPS. Therefore, results obtained with recombinant proteins have to be interpreted carefully, and recent studies came to the conclusion that some of the effects described were mediated by contaminating LPS (Bausinger et al. 2002).

However, RSV-F protein, after protease digestion, exhibited a diminished activity, indicating an interaction of this proteinaceous ligand with TLR-4. For the large and quite diverse family of HSPs, which may be viewed as sensors for necrosis, it has been shown that they also activate innate immune cells (reviewed in Vabulas et al. 2002). For HSPs of both bacterial and mammalian origin, TLR involvement in signaling has been proposed, with human HSP60 and Gp96 being the most prominent ones (Vabulas et al. 2001). The regulation of the host's innate immune response by proteins released by cells may be explained by the above-mentioned 'danger model', with HSPs indicating tissue injury or imbalance of hemostasis. HSPs activate macrophages and DCs and evidence has been obtained that both CD14 and TLR-2, as well as TLR-4, may be involved (Asea et al. 2002).

Toll-like receptor 5

BACTERIAL FLAGELLIN IS THE AGONIST OF TLR-5

Many enteric bacteria possess flagella responsible for motility and directed movement. The flagellum consists of a filament and a hook with the filament being made up of 11 flagellin monomers (reviewed in Smith and Ozinsky 2002). This 55-kDa flagellin protein has been shown to be a potent inducer of inflammation. Flagellin has been recently demonstrated to act as an agonist for another member of the TLR family, TLR-5 (Hayashi et al. 2001). Besides many enteric gram-negative bacteria, gram-positive *Listeria* spp. and spirochetes also contain flagellin, potentially leading to an interaction with TLR-5.

The signal transduction cascade, as has been shown for the other members of the TLR-family, involves MyD88 and NF-κB (Hayashi et al. 2001). Next to mammalians, flagellin is also detected by the immune system of insects and plants. In *Arabidopsis*, a receptor-like kinase termed FLS2 has been identified which interacts with flagellin (Gomez-Gomez and Boller 2000). Interestingly, FLS2 exhibits similarities with TLRs over the presence of LRRs within the extracellular domain. Therefore, recognition of bacterial flagellin appears to be a ubiquitous mechanism of innate immune responses.

POTENTIAL CLINICAL IMPLICATIONS OF TLR-5 FOR GASTROINTESTINAL DISEASES

Intestinal epithelia are only weakly responsive to LPS; however, they react with strong cytokine release on exposure to flagellin (Gewirtz et al. 2001b). TLR-5 appears to be expressed exclusively on the basolateral surface of intestinal cells (Gewirtz et al. 2001a). Therefore, flagellin has to be translocated from the luminal to the basolateral surface in order to elicit immune responses. Pathogenic *Salmonella* spp. translocate into the epithelium, whereas commensal *Escherichia* spp. do not (Gewirtz et al. 2001a). Thus, basolateral expression of TLR-5 might represent a mechanism to distinguish pathogenic from colonizing bacteria. Furthermore bacteria have developed mechanisms to regulate flagellin expression in order to evade TLR-5 recognition, i.e. the human pathogen *Listeria monocytogenes* suppresses flagellin expression at 37°C, whereas the non-pathogenic species *L. innocua* does not (Kathariou et al. 1995).

Toll-like receptors 7, TLR-8, and TLR-9

IMIDAZOQUINOLINES AS LIGANDS FOR TLR-7 AND TLR-8

Toll-like receptors TLR-7, TLR-8, and TLR-9 are closely related. TLR-7 and TLR-8 have been shown to recognize antiviral compounds, the imidazoquinolines, such as imiquimod and R-848 (Hemmi et al. 2002; Jurk et al. 2002), which are commonly used for treatment of anogenital warts caused by human papilloma virus. Recently it has been shown that TLR-7 and -8 recognize single-stranded, V-rich viral RNA (Heil et al. 2004; Diebold et al. 2004; Lund et al. 2004). TLR-9 recognizes bacterial DNA as outlined below. Signal transduction

through these receptors, as has been shown for TLR-4 and TLR-2, also involves MyD88 (Hemmi et al. 2000, 2002).

RECOGNITION OF BACTERIAL DNA BY TLR-9

Over the few last years the discovery was made that bacterial DNA differs from eukaryotic DNA in that it exhibits unmethylated CG-rich regions (commonly referred to as 'CpG'). Oligonucleotides containing certain typical nucleotides have been shown to exhibit extensive immunostimulatory capacities (Sparwasser et al. 1997; Krieg 2002). TLR-9 recognizes bacterial DNA, as revealed by studies employing TLR-9-deficient mice that could not be stimulated by CpG oligonucleotides for proinflammatory activation (Hemmi et al. 2000).

TLR-9 is predominantly expressed in plasmacytoid DCs (pre-DC2), and stimulation with CpG-DNA leads to production of high levels of IL-12, initiating a Th1 response. This makes CpG motifs that interact with TLR-9 interesting candidates for immunization strategies (Wagner 2002). In addition, CpG motifs may in the future play a role in gene therapy and cancer immunization strategies (Krieg 1999). It is obvious that, during infections treated by antibiotics, bacterial DNA is released; however, the precise role of CpG-DNA in the pathogenesis of inflammatory diseases or septic shock is still not completely elucidated. In contrast to other TLRs, TLR-9 is not found on the cell surface, but within endosomes (Ahmad-Nejad et al. 2002).

SIGNAL TRANSDUCTION CASCADE INDUCED BY TLR–LIGAND INTERACTION

As mentioned above, there are numerous homologies in the signaling pathways of human TLR activation, drosophila Toll protein, and even plant R-protein signaling (Lemaitre et al. 1996; Kimbrell and Beutler 2001). All systems initially appear to require LRR-containing molecules and, in order to initiate signaling, the presence of TIR domains is essential (Fluhr and Kaplan-Levy 2002). In addition, the human IL-1 signaling pathway displays many similarities to the TLR signaling, which may reflect the ability of the host to amplify certain responses to PAMPs via host molecules such as IL-1, released by immune cells (O'Neill and Dinarello 2000). The homologies among vertebrates, insects, and plants are numerous, and are present basically in every step of signaling. In the following section only the main pathways of TLR signaling in humans are shown.

Myd88-dependent pathways

The signal transduction cascade activated upon interaction of LPS with the TLR-4–CD14–MD-2 receptor complex, as an example for typical and largely similar TLR signaling, is shown in Figure 4. MyD88 is an adaptor molecule containing a TIR domain involved in signaling induced by many receptors of the TLR family (Takeuchi and Akira 2002). A difference exists in the additional utilization of the Mal/TIRAP protein mentioned in detail below and termed 'MyD88 independent' (reviewed in O'Neill 2002). Next to the TIR domain, MyD88 also contains a 'death domain' that is found in the downstream signaling molecule IL-1R-associated kinase (IRAK) (Cao et al. 1996). MyD88 activation after interaction of PAMP ligands with its specific TLR and subsequent multimerization is followed by an activation of IRAK and TNF receptor-associated factor 6 (TRAF-6), a member of a family of proteins involved in TNF signaling (Lomaga et al. 1999). Upon this activation, NF-κB dimers are formed involving the NF-κB-inducing kinase (NIK) (Malinin et al. 1997). After inactivation of inhibitory factor I-κB by I-κB kinase (IKK) (DiDonato et al. 1997) NF-κB translocates to the nucleus initiating transcription of genes encoding for, for example, proinflammatory cytokines.

Recruitment of TRAF-6 also leads to activation of 'evolutionarily conserved signaling intermediate in Toll pathways (ECSIT)', which in turn activates mitogen-activated protein (MAP)/extracellular stress-related kinas (eerk) kinase kinase (MEKK1), thus forming a link between Toll-mediated signaling and the MAP kinase pathways (Kopp et al. 1999). These pathways are commonly referred to as 'MyD88-dependent pathways' and seem to be involved in signal transduction by several other TLRs. Furthermore, there is evidence for another signal transduction pathway involving Rac1/PI3K/AKT, leading to the translocation of NF-κB (Arbibe et al. 2000). This pathway has originally described for TLR-2 ligands; however, recent data suggest that it may also play a role in TLR-4-mediated signaling (Ojaniemi et al. 2003).

MyD88-independent

The observation that MyD88-deficient mice at least partially respond to LPS led to the hypothesis of MyD88-independent signal transduction by TLR-4 (Kawai et al. 1999). Meanwhile, a novel TIR-domain-containing adaptor protein (TIRAP) has been described, which has been termed by others 'MyD88 adaptor-like' (Mal) (Horng et al. 2001). As TIRAP/Mal plays no role in IL-1R-mediated signaling, it represents a bifurcation between these pathways. The TIRAP/Mal knock-out mouse confirmed this bifurcation and led to the discovery that TIRAP/Mal is apparently involved in TLR-4, TLR-2, TLR-1, and TLR-6 signaling, but not in signaling brought about by activation of TLR-5, TLR-7, and TLR-9 (Horng et al. 2002; Yamamoto et al. 2002).

Recently, another MyD88-independent pathway has been discovered which leads to the activation of interferon regulatory factor-3 (IRF-3, Kawai et al. 2001). At least

three other TIR-domain-containing adaptor proteins exist (reviewed in O'Neill et al. 2003). Two of them, termed TRAM and TRIF have recently been shown to mediate the Myd-88 independent activation of IRF-3.

LINKS TO ADAPTIVE IMMUNITY

Antigen presentation

One major task of the cells of the innate immune system is to screen for pathogen-associated patterns and subsequently detect and kill invading microorganisms as first-line defense. APCs, as mentioned above (
Processing and presentation of the antigen by the class II histocompatibility system; and MHC class I antigen processing system), also act as a link between innate and adaptive immunity by presenting antigens to lymphocytes, which is extensively covered in other chapters of this volume. This link is in particular represented by immature imDCs (see above under Cells of the innate immune system), with interstitial imDCs being most important. These cells reside within peripheral tissues and scan their environment via endocytosis. After having contact with a wide variety of ligands, mainly via TLRs, they undergo maturation (reviewed in Banchereau and Steinman 1998).

PAMPs recognized by imDCs involve LPS, CpG-DNA, lipoproteins, and peptidoglycan (reviewed in Takeda et al. 2003). Maturation involves the expression of MHC molecules as well as CD80/CD86; furthermore proinflammatory cytokines, such as IL-12, are secreted. Mature DCs travel to lymph NODs and present processed antigen to T lymphocytes, initiating adaptive immune responses.

Type 1 interferons

Another link between innate and adaptive immunity is represented by plasmacytoid or type 1 pre-DCs. These cells, as shown above, express TLR-7 and TLR-9 and secrete type 1 interferons upon stimulation with adequate ligands (Kadowaki and Liu 2002). These cytokines, besides directly inhibiting viral replication and stimulating macrophages and NK cells, also activate T and B lymphocytes. They enhance proliferation of CD8 T lymphocytes, enhance the survival of T cells in general, and elicit antibody production by B lymphocytes. Obviously, type 1 interferons are crucial for immune responses against viral infections; however, they have also been described to act against bacteria and protozoa.

A TWO-STEP MODEL OF PATTERN RECOGNITION

Although the discoveries of the last few years improved understanding of pattern recognition, the general mechanism is far from being completely understood. As outlined in previous chapters, the diversity of microbial ligands is large and there are only first real molecular similarities, which allow for a definition of 'patterns'. Here, a hypothetical two-step model is proposed where, on one the hand, charged molecules are sensed, followed by a fine recognition system focusing on atypical lipids.

As described above, the PRR CD14 is able to bind a variety of ligands, including LPS, LTA, and triacylated lipopeptides. The structure of these ligands is quite different: LPS is a glycolipid with a lipid part and a polymeric part made up of carbohydrates (Raetz and Whitfield 2002). The lipid part of LPS, lipid A, is substituted with up to six fatty acids and exhibits a high degree of polarity as a result of its phosphate content (Figure 6). In contrast, LTA of *Staphylococcus aureus* is a glycolipid with a lipid anchor, being composed of glycerol and two fatty acids (diacylglycerol) and fewer phosphate charges. The polymeric region mainly consists of polyglycerophosphate, partially substituted with carbohydrates (Schroder et al. 2003). Lipopeptides are not glycolipids at all, but are amphiphiles bearing diacylglycerol linked to a peptide chain via cysteine. All these molecules are recognized by CD14 and LBP. Therefore, LBP and CD14 may represent a 'first-line' pattern recognition system shuttling amphiphiles to their receptor complexes.

Cellular PRRs such as the TLRs are able to discriminate further these molecular patterns with TLR-4 interacting with LPS, whereas TLR-2/TLR-6 dimers interact with LTA (and diacylated lipopeptides) and TLR-2/-TLR-1 dimers interact with triacylated lipopeptides (Takeuchi et al. 2001). Following this principle, TLRs would be regarded as 'second-line' PRRs initiating a more specific response to different patterns. This is reflected by the fact that the TLR-4-mediated response differs from that initiated by TLR-2 by involving IRF-3. A similar model can be proposed for the TLRs discriminating different types of nucleic acid which are TLR-3, TLR-7, and TLR-9.

CLINICAL IMPLICATIONS AND CONCLUSIONS

Exploitation of pattern recognition for therapy?

As a strong inflammatory reaction is widely viewed as playing a role in the pathology of sepsis and septic shock, interfering with innate immune responses has for many years been the focus of experimental sepsis therapy. Some of these approaches, which all failed to improve sepsis outcome, now show surprising results in the treatment of chronic inflammatory diseases. Interfering with TLR signaling is thus very likely to be the focus of a next generation of novel therapeutic strategies for both types of diseases (Beutler 2003).

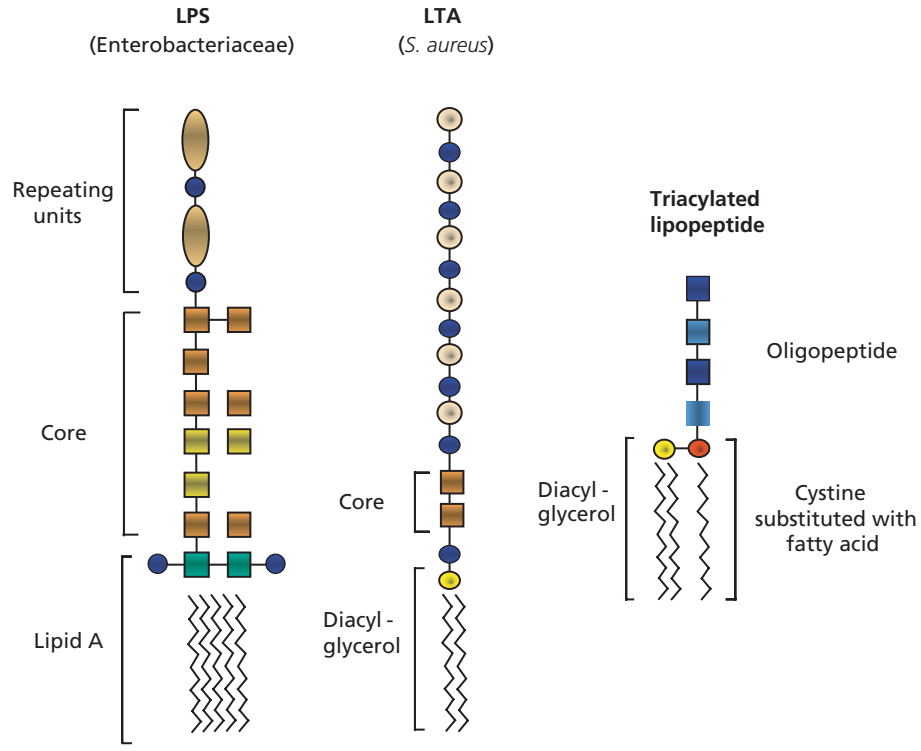

Figure 6 *Structural comparison of CD14 ligands. To attempt to define the structural requirements of a pathogen-associated molecular pattern (PAMP), here the simplified structures of lipopolysaccharide (LPS, as found in Enterobacteriaceae), lipoteichoic acid (LTA, from* Staphylococcus aureus*) and triacylated lipopeptide are compared: LPS is a glycolipid composed of a lipid part termed 'lipid A', a carbohydrate core region, and carbohydrate repeating units. Lipid A part contains up to six fatty acids. Major changes in this composition largely reduce the immunostimulatory capacity of LPS. LTA is glycolipid with a simple diacylglycerol lipid anchor, a small core region, and a polymeric backbone of polyglycerophosphate. In contrast, triacylated lipopeptides are diacylglycerols linked to cystine, which is substituted by a third fatty acid and linked to an oligopeptide.*

The LPS-inhibiting PMN protein BPI binds bacterial LPS, and in addition is bactericidal. BPI does not transfer LPS to any other receptor, leading to subsequent signal transduction and cytokine release, and therefore a potential therapeutic effect during infections with gram-negative bacteria was assumed. The recombinant amino-terminal part of BPI (rBPI21) has been applied to children with meningococcemia, which is usually associated with high levels of LPS in the bloodstream. Within the first phase I/II trials positive effects of administration of rBPI21 were observed (Giroir et al. 1997), and a phase III study came to the result that complications were less frequent among children receiving rBPI (Levin et al. 2000).

Although final results are currently not available, the concept of an early blocking of a key PAMP appears to be promising. Application of high concentrations of LBP may be an additional approach for inhibiting LPS-induced inflammatory responses (Lamping et al. 1998; Zweigner et al. 2001). LBP as an acute phase serum protein has a longer half-life compared with BPI and also inhibits effects of LPS and other PAMPs in concentrations found in serum. The host releases large quantities of LBP during the acute phase, apparently to achieve inhibition of inflammation brought about by PAMP–PRR interaction.

Genetic polymorphisms of PRRs and their impact on disease

Genetic polymorphisms, also referred to as 'nucleotide polymorphisms' (SNP), are frequent variations within a gene, which are found at least among 1 percent of individuals within a population. SNPs may have an impact on protein function; however, most SNPs reported so far are 'silent'. The relationship of genetic variations among humans and their susceptibility to disease is currently often investigated in order to identify high-risk populations and subsequently to be able to prevent diseases in these populations by specific prophylaxis.

CD14 AND LBP SNPs

During the past few years, several SNPs of PRRs were reported, including CD14 and LBP. For CD14, two polymorphisms within the promoter were reported, with one (Cys159Thr) being correlated with incidence of septic shock (Gibot et al. 2002), whereas another (Cys260Thr) apparently had no impact on the incidence of sepsis in trauma patients (Heesen et al. 2002). With regard to LBP, two SNPs were identified which were both correlated with a worsened outcome in patients with sepsis (Hubacek et al. 2002).

TOLL-LIKE RECEPTOR SNPS

Shortly after the identification of TLR-4 as the receptor for LPS, SNPs within the TLR-4 gene were described. These polymorphisms, Asp299Thr and Thr399Ile, were initially reported to be associated with decreased asthmatic reactions to inhaled LPS (Arbour et al. 2000). Meanwhile, evidence has been presented that the Asp299Thr SNPs may also be associated with the incidence of sepsis (Lorenz et al. 2002). These SNPs were mainly investigated with regard to a potential increase of susceptibility to infection. However, a decreased incidence of TLR-4 SNPs was found among patients with atherosclerosis (Kiechl et al. 2002), indicating that the limited recognition of pathogens may influence the course of a disease in a beneficial manner. SNPs were also reported for TLR-2 (Lorenz et al. 2000) and TLR-9 (Lazarus et al. 2003); however, their potential impact on human infectious diseases has not been conclusively investigated yet.

THE NOD2/*CARD15* SNPS

A striking correlation between an SNP of a PRR and disease susceptibility has been found for several mutations in the NOD2/*CARD15* gene and the incidence of Crohn's disease, which is a chronic inflammatory disease of the gastrointestinal tract occurring as frequently as 1 per 1000 in western countries (Hugot et al. 2001; Ogura et al. 2001a). Furthermore, the same mutations were found to be associated with 'Blau syndrome', a rare autosomal dominant disease consisting of uveitis, arthritis, and skin rash (Miceli-Richard et al. 2001). As mentioned above, several lines of evidence point in the direction that NOD2/*CARD15* acts as an intracellular PRR recognizing LPS or bacterial MDP (Bonen et al. 2003; Girardin et al. 2003; Inohara et al. 2003).

On the other hand, the NOD proteins similar to many of the related family members contain the caspase recruitment domain centrally involved in apoptosis regulation. It has thus been suggested that disturbance of NOD2 does not change pattern recognition but changes apoptosis regulation (Beutler 2001). This would correspond to the fact that anti-TNF treatment is highly efficient in Crohn's disease patients because TNF is a major apoptosis regulator. Recently, for Crohn's disease another, NOD2-independent genetic linkage has been found; the nature of the gene is, however, currently not known (Hampe et al. 2002).

Studies with different ethnic groups confirmed a role of NOD2/*CARD15* for Crohn's disease, ruling out an involvement in ulcerative colitis (Hampe et al. 2001). Ulcerative colitis, in contrast, was recently found in a small study to be associated with a polymorphism in the CD14 promoter, further supporting the concept of PRR SNPs being responsible for chronic inflammatory diseases of the gastrointestinal tract (Obana et al. 2002). The variation among different ethnic groups is reflected by one study showing the absence, in Japanese Crohn's disease patients, of the NOD2/*CARD15* mutations found in European populations (Kimouchi 2003). A recent study revealed an additional SNP in NOD2/*CARD15* among Ashkenazi Jews which also predisposes to the development of Crohn's disease (Sugimura et al. 2003).

New members of the CARD-containing protein family have recently been identified and several missense mutations have been found to be associated with rare inflammatory diseases, such as Muckle–Wells syndrome, familial cold urticaria, and chronic infantile neurological cutaneous and articular syndrome (McDermott 2002; Albrecht et al. 2003).

Most studies performed so far that investigate the potential effect of SNPs on the course of a particular disease focused on genetic variations of only a few proteins, including cytokines. However, the development and course of a bacterial infection are most probably a multifactorial event. Therefore, future studies investigating several SNPs in parallel and employing high-throughput technologies such as gene arrays may clarify whether SNPs of PRRs really influence the incidence and course of infectious and inflammatory diseases.

CONCLUSION

Pattern recognition is a key feature of the host's repertoire to react early to encounters with pathogens. Innate immunity most probably has an impact on both acute infectious disease complications, such as septic shock, and chronic illnesses caused by microorganisms. Innate immune responses are elicited by microbial compounds released from organisms, and thus cannot be 'treated' successfully by the application of antibiotics. APCs possess the ability to check the environment for these and other danger signals and orchestrate a response bridging innate and adaptive immunity. Major discoveries of the last 5 years include central host receptors of the Toll-like receptor family and their function. These results may lead to novel intervention strategies in acute and chronic infectious diseases that are currently not treatable by antibiotics. Genomic analyses confirm a central role of PRRs for incidence and course of infectious diseases. Intense basic and clinical research, with the help of modern molecular technologies, is, however, needed in order to exploit this growing field of immunology successfully.

Caspases	3	Acknowledgments	8
Basic cellular mechanisms and regulation	5	References	8

INTRODUCTION

In multicellular organisms, cells often die by apoptosis. This form of death occurs as a physiological event in the organism's tissues, where it ensures the elimination of unwanted cells and maintains tissue homeostasis. Apoptosis is an active process, i.e. the cell itself produces the effector proteins that kill it. For this reason, apoptosis is often compared to a cell 'suicide' (Hengartner 2000).

Characteristic morphological alterations accompany apoptosis (Mills et al. 1999; Hengartner 2000). In the nucleus, the chromatin condenses and accumulates at the level of the nuclear membrane. Cytoplasmic shrinkage and plasma membrane blebbing are also evident. Membrane blebs can ultimately pinch off the cell, forming vesicles called apoptotic bodies which contain cell organelles and nuclear material. These morphological alterations are distinct from the ones observed during necrosis, a form of cell death that follows accidental injury. In contrast to necrosis, there is no cytoplasmic swelling, and the integrity of the cell organelles is conserved until the late stages of apoptosis.

During apoptosis, the nuclear DNA is cleaved at the internucleosomal region, generating fragments ranging from 180 to 200 base-pairs. These fragments produce a typical 'ladder' when resolved on agarose gels. The surface of the cell is also modified. Phosphatidylserine, an amino-phospholipid normally restricted to the inner leaflet of the plasma membrane, flips to the outer leaflet. These changes allow phagocytes to recognize and remove apoptotic cells efficiently. Until their latest stages, apoptotic cells, however, display no changes of their plasma membrane integrity. This characteristic, together with the efficient clearance process mediated by phagocytes, ensures that the apoptotic cell does not release its contents.

THE INDUCTION OF APOPTOSIS: EXTRINSIC VERSUS INTRINSIC PATHWAYS

Apoptosis can occur as a consequence of: (1) extracellular stimulation via the engagement of death receptors present at the surface of the cell (e.g. Fas/CD95 or tumor necrosis factor (TNF) receptor), (2) changes in the transcriptional control (glucocorticoids), (3) disruption of organelles or DNA lesions induced, for example, by ionizing radiation or chemotherapy reagents, and (4) absence of trophic factors (reviewed in Hengartner 2000).

These stimuli activate two major cellular pathways controlling the occurrence of apoptosis (Figure 8.1): The extrinsic pathway is activated by extracellular stimuli such as the binding of death receptor ligands to their cognate receptors on the cell surface. In contrast, the intrinsic pathway is initiated as a consequence of many cell stresses (Figure 1). Although these two pathways are initiated and controlled in distinct fashions, two systems play a key role in their transduction: (1) mito-

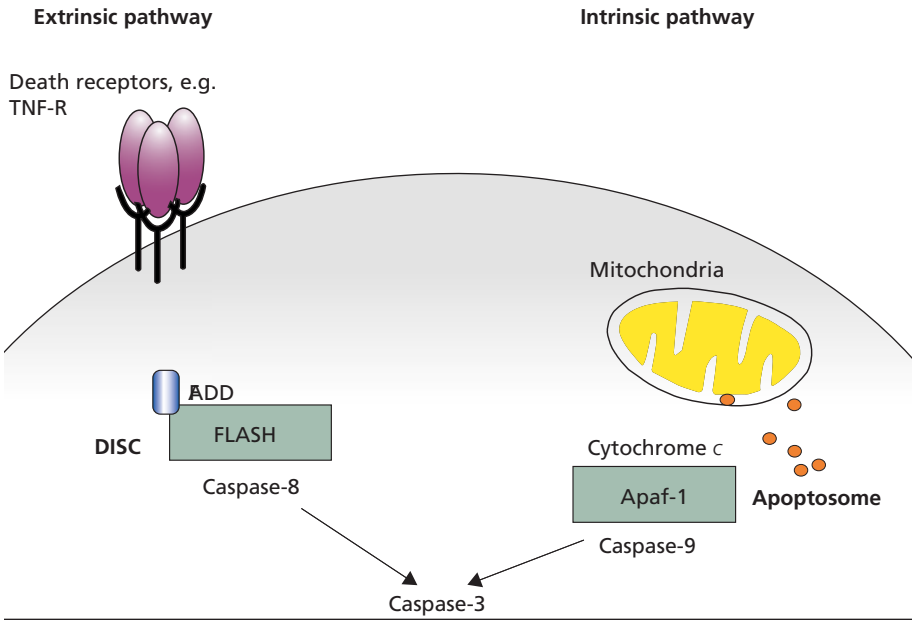

Figure 1 *Key components of the apoptotic pathway in mammalian cells. Two major pathways control the occurrence of apoptosis: one, called the intrinsic pathway, is activated by extracellular stimuli, e.g. the binding of death receptor ligands to their cognate receptors on the cell surface. These receptors transduce their death signal via adaptor proteins. These adaptor proteins mediate interactions between participants of the apoptotic cascade, e.g. the adaptor protein FADD is recruited by the activated tumor necrosis factor α (TNF-α) receptor. It in turn recruits and activates the initiator caspase caspase-8. In contrast, the intrinsic pathway is initiated as a consequence of cell stresses. A key role is played by the mitochondrial release of factors such as cytochrome c, activating the formation of a protein complex called apoptosome. The apoptosome contains the initiator caspase caspase-9 complexed with apoptosis protease-activating factor-1 (Apaf-1). Both the intrinsic and the extrinsic pathways activate the common downstream executioner caspase caspase-3. This executioner caspase is ultimately responsible for the cleavage of many cellular substrates.*

chondria and (2) caspases. In the following paragraphs, we summarize what is known about these two systems.

MITOCHONDRIA

Mitochondria are membrane organelles localized in the cytoplasm of most eukaryotic cells. They are formed by two membranes delineating an intermembrane space and the mitochondrial matrix. Mitochondria contain multiple enzyme and protein complexes involved in respiration and energy metabolism, at the level of the inner membrane and in the matrix. They also contain several factors, the release of which into the cytosol contributes to apoptosis: cytochrome *c*, the flavoprotein AIF, Smac/Diablo, HtrA2/Omi, endonuclease G, and some pro-caspases (Kroemer and Reed 2000). Cytochrome *c* is the mitochondrial factor with the best documented contribution to apoptosis induction. Upon its release from the mitochondrial intermembrane space, it serves as a cofactor for the assembly of the apoptosome and the activation of caspase-9 (see later). The mitochondrial outer membrane (MOM) is normally only permeable to solutes of small size, i.e. molecular weight or $M_r < 1.5$ kDa, and not to proteins such as cytochrome *c* (Kroemer and Reed 2000). An increased permeability of the MOM occurs early in the course of apoptosis. How apoptogenic stimuli are converted into changes in the permeability of the MOM is controversial, but different models have been proposed (Kroemer and Reed 2000), implicating either the formation of pores in the MOM or its complete rupture.

The proteins of the Bcl-2 family play a key role in regulating mitochondrial permeability (Cory and Adams 2002). In mammals, there are at least 20 relatives of the protein Bcl-2 (Figure 2). These proteins share at least one conserved Bcl-2 homology (BH) domain, BH1–4. Members of the Bcl-2 family can be classified into different subtypes: the most evident classification is based on their opposing functions: (1) the pro-survival family and (2) the pro-apoptotic family.

The pro-survival members of the Bcl-2 family

Bcl-2 and Bcl-XL are the best-characterized members of this family. These proteins share a carboxy-terminal membrane-targeting sequence. Bcl-XL is predominantly located in the MOM, whereas Bcl-2 has a broader membrane distribution, including the endoplasmic reticulum and nuclear envelope (Kaufmann et al. 2003). The pro-survival members of the Bcl-2 family are probably required in every cell of the organism in order to

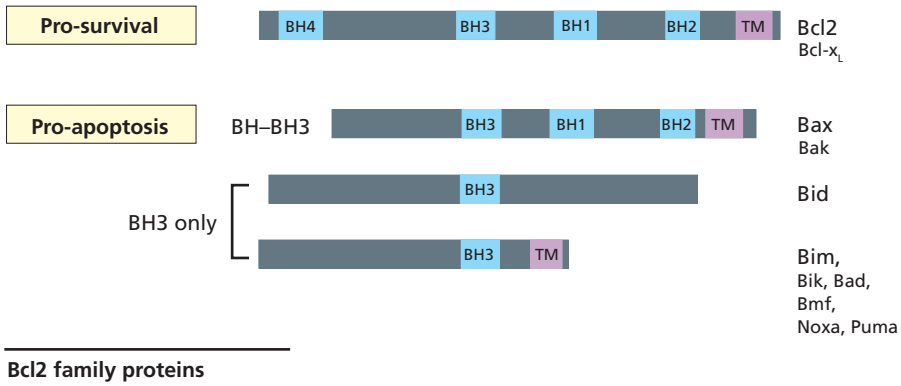

Figure 2 *Bcl-2 proteins. Proteins of the Bcl-2 family are often classified into anti- and pro-apoptotic subfamilies. They share some conserved domains (BH1–BH4), and hydrophobic carboxy-terminal membrane-targeting domain. The BH1–BH3 domains allow the members of the Bcl-2 protein family to associate to each other. The BH3 domain is present in all the members of the Bcl-2 family – it is essential for the pro-apoptotic function of the proteins Bax and Bak. The members of the BH3-only subfamily, such as Bad and Bid, function upstream of Bax/Bak. The BH3-only proteins constitute cellular sentinels, being able to activate the Bax/Bak system in response to a variety of death-inducing stimuli. Bcl-2 contains a BH4 domain which allows its interaction with other proteins. A caspase-cleavage site in this region eliminates this domain, thereby converting Bcl-2 into an apoptosis-promoting protein.*

prevent the spontaneous occurrence of apoptosis. Therefore, they play a critical function in tissue homeostasis.

The pro-apoptotic members of the Bcl-2 family

This family can be further separated into a BH3-only subfamily (Bad, Bid, Bim, Bmf, Noxa, Puma), and a BH1–3 subfamily (Bax and Bak) (reviewed in Cory and Adams 2002). The proteins Bax and Bak constitute the BH1–3 subfamily. Genetic evidence supports their role as core components of the apoptotic machinery, because Bax/Bak double knock-out cells are resistant to most apoptotic stimuli (Wei et al. 2001). The members of the BH3-only subfamily function upstream of Bax/Bak (Cheng et al. 2001; Zong et al. 2001). The BH3-only proteins constitute cellular sentinels, able to activate the Bax/Bak system in response to a variety of death-inducing stimuli. In a living cell, they are normally kept in check by different mechanisms, including sequestration at the subcellular level (interaction with the cell cytoskeleton in the case of Bim and Bmf), post-translational modifications (phosphorylation in the case of Bad, proteolytic processing in the case of Bid), or regulation at the transcriptional level (Noxa and Puma) (review in Cory and Adams 2002).

Kuwana et al. (2002) recently reported the use of a cell-free assay using purified components to reconstitute the permeation of the MOM by the protein Bax in vitro. In this system, Bax added to liposomes mimicking the composition of the MOM could permeate them to large-molecular-weight dextran molecules. This process occurred in the absence of any intrinsic mitochondrial proteins, but required the lipid cardiolipin (Kuwana et al. 2002). During apoptosis, protein efflux from mitochondria might be a consequence of local reorganization of the lipids in the MOM, driven by the proapoptotic protein Bax. This lipid reorganization might also cause the mitochondrial fragmentation that occurs during apoptosis (Karbowski et al. 2002).

The members of the pro-survival family of Bcl-2 proteins are able to bind directly and counteract the effect of the pro-apoptotic family members. In addition, they could protect cells from apoptosis independently of their mitochondrial effect (Kaufmann et al. 2003). Although the mechanisms involved are not yet clear, they may directly inhibit caspases (Marsden et al. 2002).

Clearly, many different events take place in the apoptotic mitochondria, and it is not yet possible to establish a causality link between them. Lately, a phenomenon known as the mitochondria-permeability transition (MPT) occurs. It is caused by the opening of a pore formed at the contact of the mitochondrial outer and inner membranes. This pore results in a drop in mitochondrial inner membrane polarity and swelling of the matrix, causing the rupture of the MOM and its non-selective permeabilization (review in Kroemer and Reed 2000).

CASPASES

Caspases (*c*ysteine *as*partyl-specific *prot*e*ase*) are a family of proteases that play a critical role in apoptosis (review in Earnshaw et al. 1999). As their name indicates, they are cysteine proteases that cleave their substrates after an aspartate residue. Caspases are initially produced as inactive zymogens. They share a common structural organization in three domains: an amino-terminal prodomain, and two catalytic domains p20 and p10 (Figure 3).

Depending on the level at which they participate in the apoptotic program, caspases are classified as initiator or executioner. Initiator caspases play a role in the early

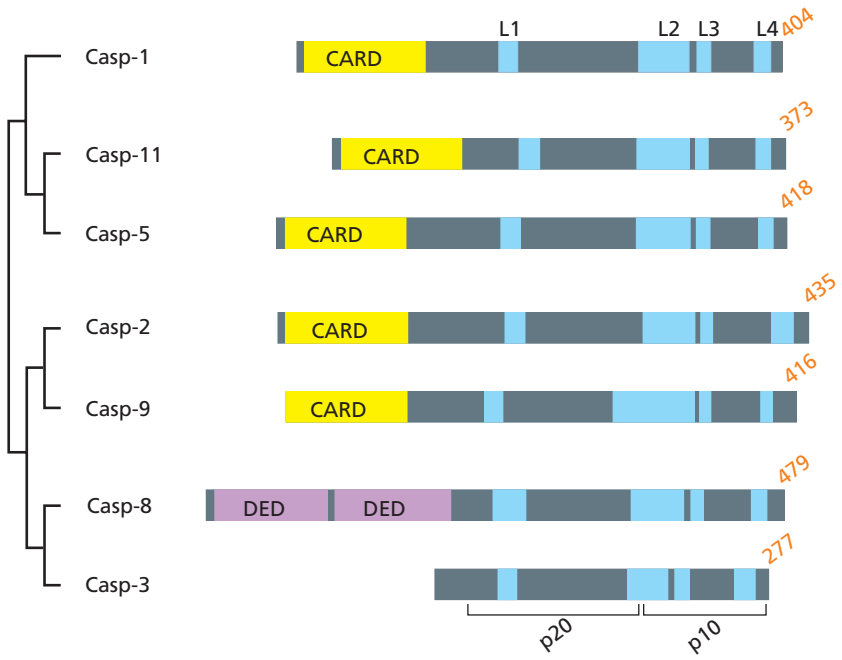

Figure 3 *Structure of caspases. Caspases are cysteine proteases that cleave their substrates after an aspartate residue. They are initially produced as inactive zymogens, and share a common structural organization in three domains: an amino-terminal prodomain, and the catalytic domains p20 and p10. Prodomain sequences vary among the members of the caspase family. In contrast to effector caspases such as caspase-3, initiator caspases such as caspase-9 or -1 contain a long amino-terminal prodomain. These prodomains contain one of the protein–protein interaction modules of the death adaptor family – death-effector domain (DED) in the case of caspase-8, caspase activation and recruitment domain (CARD) for other caspases: 1, 2, 9. These domains mediate homotypic interactions between the caspases themselves and with adaptor proteins. They therefore play a critical role in the activation of initiator caspases. (Adapted from Shi 2002.)*

phase of apoptosis, at the time the cell becomes committed to death. In contrast, executioner caspases are activated downstream of initiator caspases, and they are responsible for the morphological alterations that characterize apoptosis. These two types of caspases rely on two important mechanisms for their activation (review in Shi 2002): proteolytic cleavage of their constitutive domains and protein–protein interactions.

Proteolytic cleavage between their constitutive domains

Cleavage can be either autocatalytic or performed by other caspases. Proteolysis is the usual activation mode for the effector caspases, the prototype of which is caspase-3. Activated effector caspases cleave many proteins of the cytoskeleton, nucleus as well as other cellular organelles, thereby resulting in the characteristic hallmarks of apoptosis.

Protein–protein interactions

This activation mode is encountered with initiator caspases, which contain one of the protein–protein interaction modules of the death adaptor family in their prodomain. Members of this family are the death domain (DD), death effect or domain (DED), caspase activation and recruitment domain (CARD), and the newly described pyrin domain (PYD). Although they share no sequence homology, these domains have a common structural organization. Work so far suggests that they mediate homotypic interactions, typically between caspases and adaptor proteins (review in Shi 2002). These homotypic interactions between members of the death effector family are of paramount importance for the assembly of the large protein complexes that activate initiator caspases.

Here, we summarize only the data about the assembly of the death-inducing signaling complex (DISC), a complex that activates caspase-8, and the apoptosome, a complex that activates caspase-9. Other protein complexes contribute to the activation of caspase-1 (Martinon et al. 2002) and caspase-2 (Read et al. 2002), and are not described here.

The DISC is a large protein complex that activates caspase-8. It assembles as a consequence of the interaction between death ligands, such as TNF-α or Fas ligand, and their cognate receptors on the cell surface. TNF receptor family members contain a DD in their cytoplasmic tail, which allows them to recruit the adaptor protein FADD. FADD in turn recruits FLASH, a protein that assembles in a platform that recruits and activates caspase-8 by means of homotypic DED interactions (Imai et al. 1999).

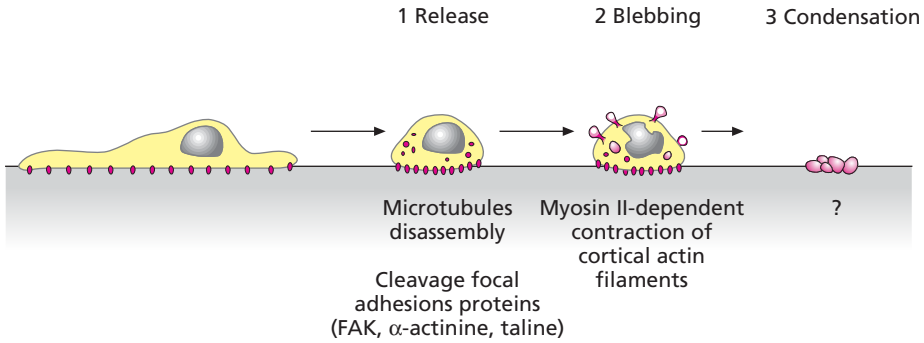

Figure 4 *The cytoplasmic execution phase of apoptosis. The cytoplasmic execution phase of apoptosis can be schematically divided into distinct steps: (1) a first step of release of the cell from its environment. The cell loses its attachment to extracellular matrix and to other cells, and thereby adopts a round appearance. The cleavage of some focal adhesion proteins, and a disassembly of the microtubule network, account for these modifications; (2) a step of blebbing, driven by the myosin II-dependent contraction of the cortical actin cytoskeleton; (3) ultimately, blebbing ceases and the cell leaves apoptotic bodies as only remnants. At that time, actin and microtubule cytoskeletons are disassembled or degraded. (Adapted from Mills et al. 1999.)*

The apoptosome is a cytoplasmic complex that assembles as a consequence of the release of cytochrome *c* from mitochondria. The cytoplasmic protein apoptosis protease-activating factor-1 (Apaf-1) is its main component. It recruits caspase-9 after binding cytochrome *c* in the presence of ATP/dATP. Pro-caspase-9 contains a CARD that mediates a specific interaction with the CARD of Apaf-1 (Shiozaki et al. 2002). A first determination of the structure of the apoptosome revealed that the Apaf-1/cytochrome *c* complex is a wheel-shaped oligomer, composed of seven Apaf-1 subunits (Acehan et al. 2002). The multimerized Apaf-1 forms a platform on which caspase-9 can dock and become activated in a CARD-dependent fashion.

Recently, a new potential aspect of caspase regulation has been highlighted: their subcellular compartmentalization. This could be an important determinant in their activation and substrate specificity, e.g. intracellular filaments recruit activated caspase-8 (Siegel et al. 1998). Nuclear import could also play a role in the compartmentalization of caspases. Candidate nuclear localization sequences (NLS) have been identified in the prodomains of caspase-1 (Mao et al. 1998) and caspase-2 (Baliga et al. 2002).

BASIC CELLULAR MECHANISMS AND REGULATION

Although caspase activation and mitochondrial permeabilization are involved in the changes observed in apoptotic cells, it is unclear to what extent these two systems are involved in the initial decision to die, and how much they contribute to reaching the 'point of no return' in the execution of death. Evolutionary considerations point to the importance of mitochondria in phylogenetically ancient organisms (Leist and Jaattela 2001). In mammals, however, this remains a controversial issue, and caspases might play a role upstream of mitochondria as initiators of the stress-induced apoptosis (Lassus et al. 2002). Nevertheless, there is a large consensus to attribute a role in the morphology of the dying cell to caspases.

Living cells normally prevent the spontaneous activation of the apoptotic systems. Among the proteins mediating this inhibitory effect, inhibitors of apoptosis (IAPs) are direct inhibitors of caspases (Shi 2002). All members of this family contain one or more BIR (baculovirus IAP repeat) domains, a domain of about 70 amino acids forming a zinc-coordinating fold. The proteins XIAP, c-IAP1, and c-IAP2 are direct caspase inhibitors: they bind to and inhibit caspases-3, -7, and -9. In addition, XIAP, c-IAP1, and c-IAP2 possess a RING-finger domain at their carboxy-termini. The RING-finger domain endows these proteins with a substrate-specific ubiquityl ligase activity toward caspase-3 and -7 (Jesenberger and Jentsch 2002). Ubiquitinylation is a post-translational modification of proteins consisting of the covalent attachment of ubiquitin, a small protein of 76 amino acids. Ubiquitin often targets proteins for degradation by the proteasome, a large cytoplasmic protease. Therefore, IAPs exert both direct and indirect inhibitory effects on caspases, by regulating their activity and controlling their destruction by the proteasome.

Decoy proteins also prevent the spontaneous activation of the apoptotic machinery in living cells. They exploit the use of protein domains involved in the apoptosis transduction pathway. Decoy proteins containing these domains prevent the spontaneous assembly of the caspase-activating complexes. This strategy is typically illustrated by the FLICE-inhibitory proteins (FLIP), proteins that possess DEDs and compete with caspase-8 for incorporation into the DISC.

Other systems appear to regulate cellular susceptibility to apoptosis although they are not directly part of its core machinery. The transcription factor NF-κB controls the synthesis of many regulators of the apoptotic pathway, such as members of the Bcl-2 or IAP family, and it therefore plays a major regulatory role during apoptosis (Karin and Lin 2002).

Once the initial brakes are relieved, activated caspases mediate the programmed demise of the cell. As more and more caspase substrates are described, we are gaining a better understanding of the key events responsible for the disposal of the cellular contents.

Important events take place in the nucleus. The DNase caspase-activated DNase (CAD) is activated as a consequence of the degradation of ICAD, its associated inhibitory protein, by caspase-3 (Enari et al. 1998; Sakahira et al. 1998). Activation of CAD is responsible for the cleavage of chromosomal DNA at the internuclosomal region, generating the typical DNA fragments visualized as a ladder on an agarose gel. Nuclear lamins, which are components of the nuclear membrane, are also cleaved. Lamin cleavage is probably partly responsible for chromatin condensation during apoptosis (Ruchaud et al. 2002).

The cytoskeleton participates actively in the morphological modifications that characterize apoptosis (Figure 4, review in Mills et al. 1999). In fibroblasts committed to apoptosis by death receptor activation, plectin constitutes an early substrate for caspase-8 (Stegh et al. 2000). Plectin, a member of the family of plakins, serves as a link among the three major constituents of the cell cytoskeleton: actin microfilaments, microtubules, and intermediate filaments. The cleavage of plectin is responsible for the early reorganization of the cytoskeleton observed in dying cells (Stegh et al. 2000). In epithelial cells, intermediate filaments (mostly of the cytokeratin family) are an early substrate of effector caspases (review in Oshima 2002). The cleavage of cytokeratins by activated caspases provides an interesting paradigm: in addition to contributing to the programmed dismantling of the cell, it probably provides a positive feedback for further caspase activation (Oshima 2002).

Membrane organelles such as the Golgi apparatus undergo fragmentation during apoptosis. The cleavage of protein p115, a key vesicle tethering protein required for the maintenance of this organelle, contributes to this fragmentation process (Chiu et al. 2002). Here, again, a cleavage product of p115 plays a key role by further amplification of the apoptotic response.

Taken together, the preliminary analysis of the apoptotic dismantling of the cell is consistent with the view that this process is highly organized, its multiple aspects being highly coordinated.

WHAT HAPPENS AFTER DEATH?

Apoptotic cells are efficiently recognized and removed by phagocytes (review in Savill and Fadok 2000). It is widely accepted that dying cells exhibit molecules that signal for their identification and clearance. A large number of cell adhesion molecules could participate in this process, although it is not yet clear which candidates really play a role in vivo.

A change in the distribution of phosphatidylserine (PtdSer), a phospholipid normally restricted to the inner leaflet of the plasma membrane, probably constitutes an important event for the recognition of apoptotic cells. In addition to the appearance of PtdSer on the outer face of the plasma membrane, apoptosis leads to the inappropriate surface localization of molecules that are normally restricted to internal cellular compartments. Many candidate receptors for PtdSer have been identified. The only candidates for which an in vivo contribution has been documented are the product of the proto-oncogene Mer (Scott et al. 2001), and the milk fat globule epidermal growth factor (EGF) 8 (MFG-E8), a secreted glycoprotein that might bridge PtdSer with integrins on macrophages (Hanayama et al. 2002). It is likely that they contribute in a cell- and tissue-specific fashion to the recognition of apoptotic cells.

Interestingly, the report of Brown et al. (2002) recently modulated the classic view that only 'positive' signals are responsible for the clearance of apoptotic cells. These authors showed that viable cells can deactivate macrophage phagocytic ability: a 'repulsive' signal follows the initial contact with the macrophage, and it is mediated by the homophilic interaction of the CD31 molecule present on both the macrophage and its prey. Apoptosis-induced disablement of this signal would promote the engulfment of non-viable cells (Brown et al. 2002).

The interface between the dying cell and the macrophage that attempts to eliminate it is an active one (review in Conradt 2002). The recognition of a dying cell triggers its phagocytosis by means of activation of effectors such as the small GTPase Rac. In return, the recognition of dying cells by macrophages could participate in the completion of the apoptotic program (Conradt 2002). Apoptotic cells signal not only toward macrophages, but also toward their neighbors: early during the apoptotic program, dying epithelial cells provoke their extrusion by an active, Rho GTPase-dependent contraction mechanism performed by their neighbors (Rosenblatt et al. 2001).

Traditionally, the recognition of apoptotic material is considered to have mostly anti-inflammatory and immunosuppressive effects (Savill and Fadok 2000). This view has been challenged recently and more work is clearly needed to determine how apoptosis influences the immune reaction. As the receptors involved in the clearance of apoptotic cells are better characterized, the role of apoptosis in inflammation and immunity will be better understood (Savill et al. 2002).

BACTERIAL-INDUCED APOPTOSIS

Bacterial pathogens induce apoptosis by a variety of mechanisms (Weinrauch and Zychlinsky 1999). One mechanism is the production of bacterial toxins, either pore-forming or with an intracytoplasmic mode of action.

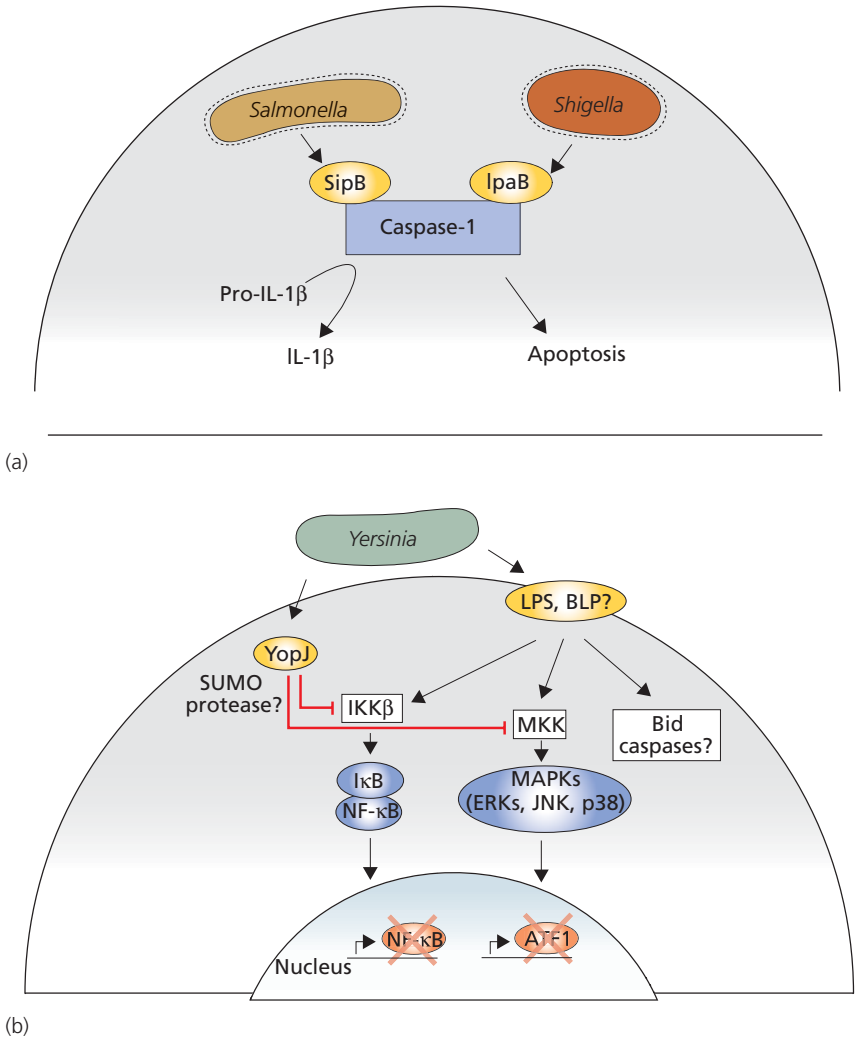

Figure 5 *Bacterial-induced apoptosis.* **(a)** Salmonella *and* Shigella *spp.-induced apoptosis.* Salmonella *and* Shigella *spp. provoke the death of macrophages by introducing, respectively, the proteins IpaB and SipB into their cytoplasm. The apoptosis that ensues is dependent on caspase-1. It is characterized by the simultaneous production and release of the proinflammatory cytokines interleukin (IL)-1β and IL-18. The molecular detail of the interactions between IpaB or SipB and caspase-1 are still unknown.* **(b)** Yersinia *spp.-induced apoptosis. The factor YopJ accounts for the ability of* Yersinia *spp. to kill its host's macrophages. YopJ has recently been shown to act as a cysteine protease, having the ubiquitin-like molecule SUMO as substrate. YopJ disrupts this post-translational modification. As a consequence, it inhibits the mitogen-activated protein kinase (MAPK) and NF-κB signaling pathways. These two pathways are used by the activated macrophages to produce proinflammatory cytokines, i.e. tumor necrosis factor (TNF)-α. As a result, macrophage death is not accompanied by the production of inflammatory mediators. Other bacterial factors recognized by surface receptors of the Toll-like receptor (TLR) family, such as bacterial lipopolysaccharide or lipoproteins, probably play a cofactor role in macrophage death induced by* Yersinia *spp.*

Other bacterial products can be secreted and translocated into host cells by means of specialized secretion systems, such as type III secretion. We have chosen to discuss here three model microorganisms, *Salmonella*, *Shigella*, and *Yersinia* spp., which induce apoptosis of macrophages as part of their pathogenic strategy.

Shigella spp are the etiological agent of bacterial dysentery, a diarrheal syndrome. This intestinal infection is an acute, inflammatory disease caused by an acute destruction of the colonic epithelium. In contrast, *Salmonella typhi* disseminates in the immune tissues of its host, causing systemic infections such as typhoid fever in humans. Early during the course of its infection, *Shigella* spp. induce apoptosis of macrophages in the lymphoid follicles of the intestinal mucosa. The bacterial protein IpaB is responsible for macrophage death. IpaB is introduced into the cytoplasm by a type III secretion apparatus. Macrophage apoptosis induced by the bacteria of the genus *Salmonella* is mediated by the bacterial protein SipB, which shares more than 40 percent sequence identity with IpaB (Hersh et al. 1999). Both IpaB and SipB induce macrophage apoptosis by activating caspase-1: macrophages from caspase-1 knock-out mice survive infection by *Shigella* (Hilbi et al. 1998) or *Salmonella* spp. (Hersh et al. 1999). In addition to its role in macrophage death, caspase-1 is also a

cytokine processor (it was initially named interleukin 1β (IL-1β)-converting enzyme, or ICE): its activation provokes, together with macrophage death, the release of the proinflammatory cytokines IL-1β and IL-18.

Caspase-1 knock-out mice infected with *Shigella flexneri* do not develop the acute inflammation that is characteristic of shigellosis (Sansonetti et al. 2000). These mice are also much less sensitive than their wild-type counterparts to oral infection, but not to intraperitoneal infection, by virulent *Salmonella* spp. (Monack et al. 2000). Caspase-1 activation and macrophage apoptosis are therefore important events in the course of shigella and salmonella infections. Both these bacteria use macrophage apoptosis as a virulence strategy to initiate an inflammatory response that probably favors their invasion of the intestinal mucosa.

The *Yersinia* genus offers another example of bacterial-induced macrophage programmed cell death. It includes three species that are pathogenic in humans: *Y. pestis*, *Y. enterocolitica*, and *Y. pseudotuberculosis*. Whereas *Y. pestis* is the causative agent of the plague, *Y. enterocolitica* and *Y. pseudotuberculosis* cause gastrointestinal syndromes, lymphadenitis, and septicemia. These symptoms appear as a consequence of the ability of *Yersinia* spp. to survive inside the lymphatic tissue of the host. In contrast to *Shigella* or *Salmonella* spp., *Yersinia* spp. are extracellular pathogens. They are able to induce macrophage apoptosis, and this apoptotic response is dependent on the bacterial protein YopJ/P (YopJ in *Y. pestis* and *Y. pseudotuberculosis*, YopP in *Y. enterocolitica*). In the macrophage cytosol, YopJ/P blocks the activation of the transcription factor NF-κB and the activity of a family of kinases: the MAPKs (Figure 5). It probably does so by cleaving the protein SUMO, a ubiquitin-like molecule that is covalently added to numerous regulatory proteins (Orth et al. 2000). NF-κB controls the transcription of genes that promote cell survival and the production of proinflammatory cytokines. In contrast to *Shigella* or *Salmonella* spp., by preventing the activation of NF-κB, *Yersinia* spp. induce macrophage apoptosis without causing inflammation. This response probably represents an adaptation to the extracellular lifestyle of *Yersinia* spp., which renders these bacteria extremely sensitive to inflammatory mediators such as IL-8, interferon-γ (IFN-γ)- or TNF-α. The simultaneous elimination of phagocytic cells and the suppression of proinflammatory cytokine production promote systemic dissemination of *Yersinia* spp. (Monack et al. 1998).

Apoptosis induction is not only induced by bacteria for purposes of pathogenicity, but is also an immune response used by the host against bacteria, in order to limit the extension of the infection. In mammals, this mechanism might particularly operate at the level of epithelia. In a mouse model of *Pseudomonas aeruginosa* pneumonia, Grassme et al. (2000) observed that bronchial cell apoptosis mediated by the cell death receptor CD95 allowed an increased survival of the animals. Apoptosis might contribute to the elimination of cells that are in contact with germs and to the prevention of bacterial dissemination. Apoptosis might therefore serve as an important mechanism preventing the establishment of 'sanctuaries' for pathogens.

Apoptosis is probably not only a mechanism that limits the pathogen's niche. It might also contribute to the initiation of a specific immune response. Following the apoptosis of *Salmonella typhimurium*-infected macrophages, bacterial antigens can be efficiently taken up and presented by bystander dendritic cells (Yrlid and Wick 2000). It is not yet clear how much the processing of antigens obtained from apoptotic macrophages contributes to the activation of antibacterial immune mechanisms. However, during the course of bacterial infection, macrophages could, by committing 'altruistic' suicide, (1) favor the recruitment of potent bactericidal effectors such as polymorphonuclear cells to the site of infection and (2) help deliver antigenic material in an efficient way to other immunocompetent cells. Apoptosis might therefore play a role in the immune response against some bacterial pathogens.

CONCLUSION

Major progress has been achieved in the field of apoptosis during the last decade. While the existence of programmed cell death has gained widespread acceptance, it has been possible to identify some key components of the death pathway. Apoptosis is now acknowledged as an important step in the pathogenicity of many diseases, including bacterial infections.

Complement deficiencies	11		

INTRODUCTION

Complement (C) is a central component of innate immunity, playing important roles in defense against pathogens and the handling of dead and dying cells and cell debris. It also influences adaptive immunity, providing a bridge between these defense systems. The C system has been reviewed and revisited scores of times over the past three decades and it is not my intention in this chapter to rehash the reviews that have gone before. Instead, I will summarize what I believe is essential for an understanding of the system and then focus on more recent developments that have made the study of C exciting again, particularly those of relevance to human disease. Along the way I will, of course, show my own biases and give undue attention to aspects that I find personally fascinating. I hope that these excursions will be excused and perhaps even entertain.

Complement comprises a group of 17 soluble plasma proteins that interact with one another in three distinct enzymatic activation cascades (the classical alternative and lectin pathways) and in the nonenzymatic assembly of a cytolytic complex (the membrane attack pathway) (Figure 1 and Table 1). It is rigidly controlled by a battery of at least 10 regulatory proteins (CReg) present in plasma and on cell membranes which together prevent damage to self and rapid consumption of C in vivo. In the following sections, the anatomy of the C system, its activation and control, the physiological and pathological roles of C and its activation, the diseases associated with defective C function, and therapies targeting C are described.

HISTORICAL ASPECTS

Complement was discovered during the last decade of the nineteenth century from studies of the capacity of immune sera to kill bacteria and lyse foreign erythrocytes. Two serum factors were required for these bactericidal and hemolytic activities: a heat-stable factor present only in immune serum and a heat-labile factor that was present in both immune and nonimmune sera (Ehrlich and Morgenroth 1899, 1900). The heat-stable factor, termed 'immune body' by Ehrlich, was of course antibody present only in the immune serum. The factor destroyed by warming the serum (a critical cut-off of 56°C was demonstrated later), Bordet and, later, Ehrlich considered 'a complement' to the killing capacity of the immune bodies, coining the name we now all know and love (Bordet 1900). Another important finding from these early studies was the demonstration that C was used up or consumed during lysis of erythrocytes, indicating that it was more than the accessory factor postulated by Ehrlich, and rather an active participant in the lytic reaction, defined by Muir as 'that labile substance of normal serum which is taken up by the combination of an antigen and its antisubstance' (Muir and Browning 1904). The multi-component nature of C was first demonstrated by Ferrata (1907) in the first decade of the twentieth century. He showed that C comprised both water-soluble (euglobulin) and insoluble (pseudoglobulin) components, later termed C′1 and C′2 respectively. Application of other fractionation techniques identified further 'components', termed C′3 and C′4, so

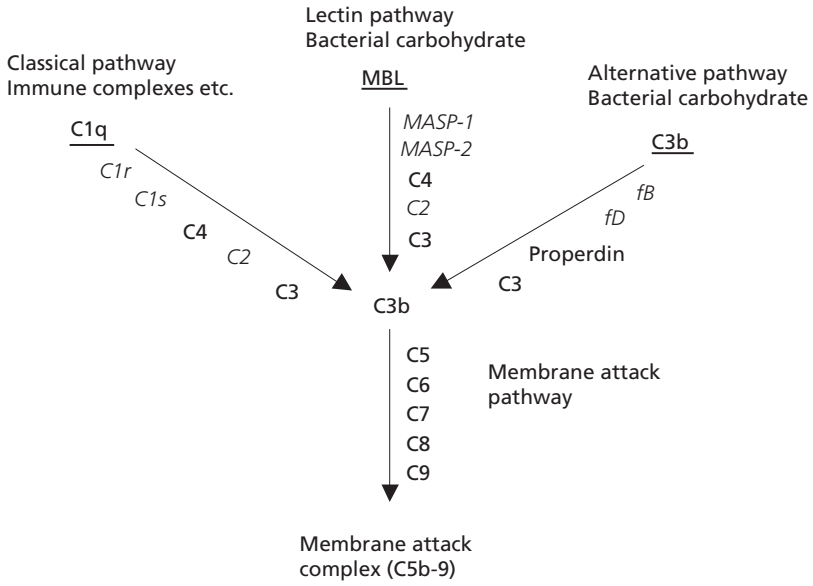

Figure 1 *The complement system. The constituent pathways of the C system and the component proteins are shown in sequential order. The initiating component of each pathway is underlined. Components that are enzymes or proenzymes are shown in italics. Abbreviations are as in the text.*

that by the mid-1920s it was clear that C comprised at least four different and separable activities from serum (Whitehead et al. 1925). However, the nature of these activities was unknown. Definitive evidence that at least some of the 'components' were protein in nature was first provided by Pillemer in his seminal work during the 1940s and 1950s, applying the new electrophoretic and ultracentrifugation techniques (Pillemer et al. 1954). These studies also revealed the presence of a second activation pathway, distinct from the antibody-triggered 'classical' pathway of Ehrlich, which was termed the 'alternative' pathway (Pillemer et al. 1954; Blum et al. 1959). Over the next two decades, pioneering use of separation methods by the group of Muller-Eberhard provided further dissection of the C system with the identification of at least nine protein components by the mid-1960s (Muller-Eberhard 1969). Complementary functional analyses, particularly from the groups of Mayer and Lepow, established the enzymatic nature of C activation and the reaction sequences from which the pathways emerged (Mayer 1965).

THE ANATOMY OF THE C SYSTEM

Complement can be activated in several different ways, reflecting the various targets for the system. The hemolytic and bacteriolytic phenomena observed by Bordet and Ehrlich were dependent on antibody that triggers activation of the classical pathway. However, pathogens and other 'foreign' targets activate C in the absence of antibody via two more recently described pathways, the alternative pathway and the lectin pathway.

Activation of the classical pathway

The classical pathway is 'classically' triggered by antibody attached to particulate antigen, although many other substances, including components of damaged cells, bacterial lipopolysaccharide (LPS), C-reactive protein (CRP), and nucleic acids, can also trigger the classical pathway in an antibody-independent manner. Attachment of immunoglobulin (IgG) antibody in sufficient density on the particle surface creates an environment in which the first component of C, C1, can bind. Not all subclasses of IgG antibodies are capable of binding C1; sequence differences in the antibody Fc (Cγ2 domain) regions influence the C1-binding site such that, in humans, IgG1 and IgG3 are strong binders, IgG2 binds weakly, and IgG4 does not bind. Classical pathway-activating capacity correlates precisely with C1 binding (Lucisano Valim and Lachmann 1991). IgM antibody is a strong binder of C1 and, because of its multimeric (pentameric) nature, does not require a high surface density to activate C. Conformational changes occur in the IgM molecule on attachment to antigen, making the Fc (Cμ3 domain) regions available for binding C1 (Perkins et al. 1991). C1 is a large multicomponent complex (molecular weight or M_r about 800 kDa), comprising a single molecule of the recognition unit, C1q, and two molecules each of the enzymatic units, C1r and C1s (Arlaud et al. 1989). The C1q molecule is a member of a growing family of proteins, the collectins, which have both collagen-like and lectin-like domains (Holmskov et al. 1994). Six subunits, each composed of three homologous chains (A, B, and C), associate along an extended collagenous tail and then

Table 1 *The component proteins of the C system*

Component	Structure	Sub-component	Plasma concn (mg/l)	(μmol/l)
Classical pathway				
C1	Complicated molecule, composed of three proteins, C1q (460 kDa), C1r (80 kDa), C1s (80 kDa) in a complex (C1qr2s2)	C1q	180	0.40
		C1r	34	0.43
		C1s	31	0.39
C4	Three chains (α, 97 kDa; β, 75 kDa, γ, 33 kDa); from a single precursor		600	2.93
C2	Single chain, 102 kDa		20	0.20
Alternative pathway				
fB	Single chain, 93 kDa		210	2.26
fD	Single chain, 24 kDa		2	0.08
Properdin	Oligomers of identical 53 kDa chains		5	0.09
Lectin pathway				
MBL/MASP	Complicated molecule, composed of three proteins, MBL (about 600 kDa), MASP-1 (93 kDa), MASP-2 (76 kDa) in a complex. Excess of MASP-1 over MBL in plasma	MBL	1[a]	0.002[a]
		MASP-1	6	0.07
		MASP-2	nk	–
Common				
C3	Two chains: α, 110 kDa, β, 75 kDa		1300	7.03
Terminal pathway				
C5	Two chains: 115 kDa, 75 kDa		70	0.39
C6	Single chain, 120 kDa		65	0.54
C7	Single chain, 110 kDa		55	0.50
C8	Three chains: α 65 kDa; β 65 kDa; γ 22 kDa		55	0.36
C9	Single chain, 69 kDa		60	0.89

a) The plasma concentration of MBL varies widely among normal individuals. The proteins that constitute the classical, alternative, and membrane attack pathways are listed. MBL, mannin-binding lectin; MASP, MBL-associated serine proteases; nk, not known. Modified from: Morgan, B.P. and Harris, C.L. 1999: *Complement regulatory proteins*. London: Academic Press.

separate to form the six globular heads, each of which represents a binding site for antibody Fc. Between the heads sits the enzymatic core, the $(C1r:C1s)_2$ complex (Figure 2). C1r and C1s are homologous single-chain molecules of M_r 80 kDa, which associate with one another and with C1q in a Ca^{2+}-dependent complex (Reid 1986; Reid and Day 1989). Upon binding to antibody through several head groups, conformational changes occur within the C1q molecule which in turn cause conformational alterations in the C1r proenzyme, triggering autocatalytic activation by cleaving a single site (R^{446}–I^{474}) in the molecule. Active C1r cleaves C1s at a single site (R^{422}–I^{423}) to activate the C1s serine protease (Arlaud et al. 1989). C1s in the activated C1 complex will cleave and activate the next component of the classical pathway, C4.

C4 is a large, plasma protein (M_r 200 kDa) containing three disulfide-bonded chains (α, β, and γ) (Schreiber and Muller-Eberhard 1974; Janatova and Tack 1981). C1s cleaves C4 at a single site (R^{737}–A^{738}), near the amino-terminus of the α chain, releasing a small fragment, C4a (M_r about 9 kDa), and exposing a labile, reactive, thioester group in the α chain of the large fragment, C4b. The thioester, formed between residues C^{991} and Q^{994} in the sequence GCGEQT, is key to the way that C acts selectively on targets (Dodds et al. 1996; Law and Dodds 1997). The exposed thioester in C4b forms covalent amide or ester bonds with exposed amino or hydroxyl groups, respectively, on the activating surface, locking the molecule to the surface. The two isotypes of C4, C4A and C4B, although identical apart from four clustered amino acids in the α chain, differ in their

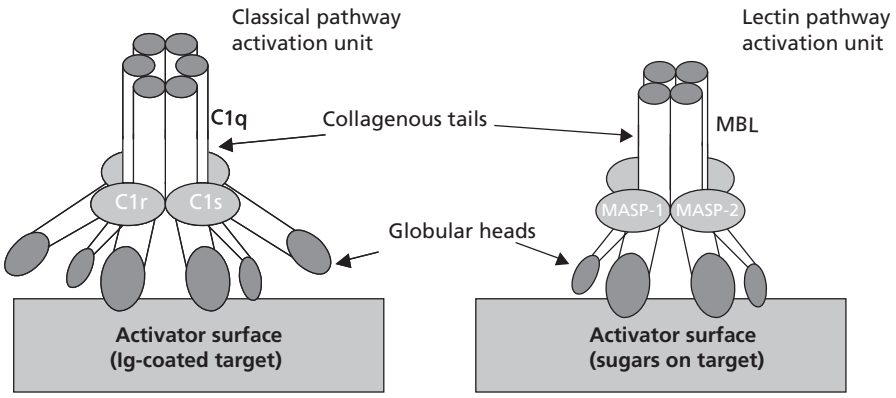

Figure 2 *The initiating molecules of the classical and lectin pathways. The activating unit of the classical pathway comprises one molecule of the multimeric C1q (itself made up of six subunits, each composed of three polypeptide chains), together with two molecules each of C1r and C1s arranged as a tetramolecular complex close to the heads of C1q. The activating unit of the lectin pathway has a very similar structure, comprising one molecule of mannan-binding lectin (MBL) (itself made up of between two and six subunits), together with two molecules each of MBL-associated serine proteases (MASP) MASP-1 and MASP-2 arranged as a tetramolecular complex close to the heads of MBL. Each unit binds an activating surface through its globular head groups, thereby triggering activation of the enzymatic components of the complex.*

surface-binding proclivities such that C4A preferentially binds amino groups and forms amide bonds whereas C4B favors hydroxyl groups and forms ester bonds (Tosi et al. 1985). The terminology used for C4 represents one of the many opportunities for confusion in the complement system, the lower case suffixes a and b denoting the fragments generated on cleavage of C4 and the upper case suffixes A and B the isotypes, both of which are cleaved by C1. Attachment of C4b is an inefficient process because the thioester is rapidly inactivated in the fluid phase by hydrolysis, effectively limiting the spread of 'active' C4b to the area surrounding the activating C1. C4b bound close to C1 provides a receptor for the next component of the classical pathway, C2, and presents it for cleavage by C1.

C2 is a single chain plasma protein of molecular weight 102 kDa (Kerr and Porter 1978). In the presence of Mg^{2+} ions, the proenzyme C2 binds membrane-bound C4b and is cleaved by C1s in an adjacent C1 complex at a single site (R^{223}–K^{224}). Cleavage is absolutely dependent on the association of C2 with C4b and fluid-phase C2 is not cleaved by C1. The larger carboxy-terminal fragment, C2a, containing the serine protease domain, remains attached to C4b to form the C4b2a complex, the next enzyme in the classical pathway, whereas C2b is released. Again, terminology is confusing. For most cleavages in C activation, the larger fragment that is required for propagation of activation is termed the 'b' fragment; for historical reasons, C2 does not follow this pattern.

C3, a 185-kDa two-chain molecule, is the most abundant of the C components (1–2 mg/ml in serum) and is essential for activity of all activation pathways (Lambris 1988). C3 attaches loosely to the C4b2a complex and is cleaved at a single site in the α-chain (R^{726}–S^{727}) by the C2a enzyme. Cleavage releases a small, biologically active peptide, C3a (77 amino acids; M_r 9 kDa), from the amino-terminus of the α chain and exposes in the large fragment, C3b, a labile thioester group formed between residues C^{988} and Q^{991} in the sequence GCGEQN. The thioester shares the properties of that in C4b and is similarly susceptible to inactivation by hydrolysis. C3b binds covalently via the thioester either to the activating C4b2a complex or to the adjacent membrane (Kozono et al. 1990; Ebanks et al. 1992). C3b bound to the activating C4b2a complex creates a new enzyme, C4b2a3b, the C5-cleaving enzyme (convertase) of the classical pathway (Kinoshita et al. 1988).

C5 is a two-chain protein of molecular weight 190 kDa, present in plasma at about 75 μg/ml (Tack et al. 1979). C5 is structurally related to C3 and C4 but lacks the thioester so it cannot bind covalently to surfaces. C5 attaches to C3b in the C4b2a3b convertase and is cleaved at a single site in the α chain (R^{733}–L^{734}) by C2a in the complex. A small, glycosylated fragment, C5a (74 amino acids; M_r about 10 kDa), is released from the amino terminus of the α chain, the large fragment, C5b, remaining attached to the convertase.

Activation of the alternative pathway

The alternative pathway provides a rapid, antibody-independent route for activation and amplification of C on foreign surfaces (Figure 3). The efficiency of alternative pathway activation results in large part from the fact that it is in a constant state of low-level or 'tickover' activation which targets all exposed surfaces (Lachmann and Hughes-Jones 1984; Law and Dodds 1990). As in the classical pathway, C3 is the central player, but three

unique proteins, factor B (fB), factor D (fD), and properdin, are also involved. During tickover, C3 in plasma is hydrolyzed to form a metastable $C3(H_2O)$ molecule which, in the presence of Mg^{2+} ions, binds fB, a single-chain (M_r 90 kDa) protein closely related to C2 and performing, in the alternative pathway, a role analogous to that of C2 in the classical pathway. Once bound to $C3(H_2O)$, fB is cleaved by fD, a highly specific and constitutively active serine protease (M_r 25 kDa) present in plasma at very low concentrations (2 μg/ml). FD cleaves fB in the $C3(H_2O)$ complex at a single site (R^{234}–K^{235}), releasing the smaller fragment Ba (M_r 30 kDa) and exposing in the larger fragment, Bb, a cryptic serine protease domain (Gotze 1986). The fluid-phase C3 convertase thus formed can now cleave plasma C3 at a single site identical to that described for the classical pathway, releasing C3a and exposing the thioester in C3b that allows covalent binding to surfaces. C3b binds indiscriminately to surfaces but further propagation continues only on so-called 'activator' surfaces such as invading bacteria. Healthy self-cells are 'nonactivator' and do not favor propagation. On activator surfaces, covalently bound C3b binds fB, enabling fD cleavage to form a surface C3bBb enzyme that cleaves more C3b, driving amplification and coating of the activating particle with C3b. Self-cells are nonactivators in part because of the expression of membrane C regulators, described below. However, it is now clear that the fluid-phase C regulator factor H (fH) is the main discriminating factor, binding and inhibiting C3bBb enzymes on nonactivators but ignoring those on activator surfaces (Jokiranta et al. 1996). Properdin, a single-chain plasma protein, also contributes to the survival of C3bBb on activator surfaces by binding and stabilizing the clustered complex (Lambris et al. 1984).

A proportion of the nascent C3b formed will attach directly to the C3bBb enzyme, creating in the trimolecular complex, $(C3b)_2Bb$, a binding site for the next component, C5, and simultaneously altering the substrate specificity of the enzyme to a C5 convertase. This enzyme binds and cleaves C5 in precisely the same way as described above for the classical pathway C5 convertase.

The lectin pathway

This newly characterized antibody-independent pathway of C is perhaps better described as a C1 bypass route because, apart from the initiating component, it is identical to the classical pathway (Gadjeva et al. 2001). The role of C1 is played by another complex molecule, structurally related to C1 and comprising a collectin recognition unit and associated serine proteases. The recognition unit, mannan-binding lectin (MBL) is a high-molecular-weight serum lectin, made up of between two and six structural units, each a trimer of a single 32-kDa chain. The subunits associate in a collagenous tail and separate into heads that form the recognition units (see Figure 2). MBL binds the simple carbohydrates

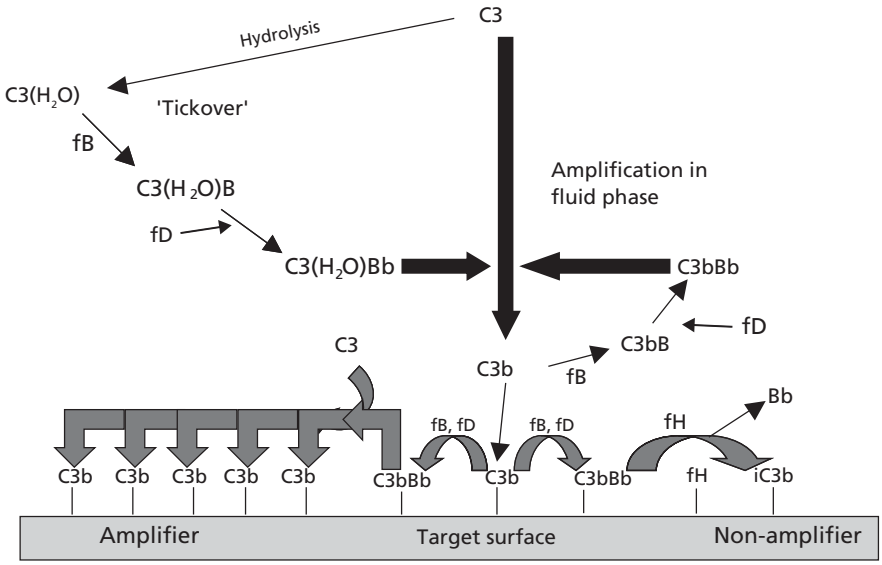

Figure 3 *The alternative pathway activation loop and the role of fH. Activation begins in the fluid phase with the slow, spontaneous hydrolysis of C3 to form $C3(H_2O)$. Binding of fB to $C3(H_2O)$ and subsequent cleavage by fD generates a fluid-phase convertase, $C3(H_2O)Bb$, that cleaves C3 to C3b. Some of the C3b formed will bind fB and perpetuate activation in the fluid phase but a proportion will bind surrounding surfaces and form C3 convertases. On nonactivating surfaces (self-cells), fH (present in the fluid phase and on the surface) inactivates the bound convertase and stops further activation. On activator surfaces, amplification proceeds unhindered and the surface rapidly becomes coated with C3b.*

mannose and *N*-acetylglucosamine present on the cell walls or envelopes of diverse pathogens, including bacteria, yeast, fungi, and viruses (Holmskov et al. 1994; Reid and Turner 1994). The enzymatic activity resides in MBL-associated serine proteases (MASP) MASP-1 and MASP-2, structural and functional homologues of C1r and C1s. Binding of the MBL–MASP complex to targets causes autolytic cleavage at a single site in MASP-1 and MASP-2 to unmask the serine protease domains. Although the precise roles of the two proteases are unclear, the weight of evidence suggests that MASP-2 in the complex is the C2-cleaving moiety. The activated MBL–MASP complex cleaves C4 and subsequently C2 in a manner identical to that described for C1 in the classical pathway. There is in vitro evidence that MASP-1 directly cleaves C3, bypassing the requirement for C4 and C2. The physiological relevance of this observation is not known. Recent evidence indicates that the ficolins, a family of lectin-like proteins present in plasma, can substitute for MBL and form C-activating complexes with the MASPs (Matsushita and Fujita 2001).

The membrane attack pathway

The membrane attack or terminal pathway involves the noncovalent association of C5b with the four terminal C components, C6, C7, C8, and C9, to form an amphipathic membrane-inserted complex, the membrane attack complex (MAC) (Muller-Eberhard 1986). The four terminal components are homologous molecules that have arisen by gene reduplication during evolution, a fact that is apparent from studies of the primitive C system of sharks (Jensen et al. 1981). Sharks generate a functional MAC from a single terminal component that most closely resembles human C9. The added complexity in mammals probably provides a more efficient targeting system to limit damage to self. The first step in MAC assembly involves the capture by C5b, still attached to the C5 convertase, of C6, a large single chain protein (M_r 120 kDa) present in plasma at about 50 μg/ml (DiScipio and Hugli 1989). A binding site newly exposed in C6 enables the C5b6 complex to capture the next component in the sequence, C7, a single chain protein (M_r 90 kDa; about 90 μg/ml in plasma) (DiScipio et al. 1988; DiScipio 1992a). Capture of C7 triggers release of the trimolecular complex from the convertase, and creates a binding site for the next component (C8), and a labile hydrophobic binding site through which C5b67 can bind tightly to the membrane. As a result of the lability of the membrane-binding site and the presence of plasma inhibitors (described below, under The membrane attack pathway), most of the C5b67 formed does not attach to membrane but 'decays' to an inactive complex that can be detected in plasma as an index of C activation. C5b67 that does bind membrane becomes tightly associated but does not disrupt the bilayer. C8, a large, heterotrimeric plasma protein (150 kDa; 80 μg/ml in plasma), binds C7 in membrane-associated C5b67, causing the tetrameric C5b-8 complex to insert deeper in the membrane and creating binding sites for the final terminal component, C9 (M_r 70 kDa; 60 μg/ml in plasma) (Sodetz 1989). C9 undergoes a major conformational change upon binding C5b-8, from a compact, globular shape to an extended conformation that traverses the membrane. As well as disrupting the integrity of the bilayer, this event exposes C9 binding sites for additional C9 molecules which in turn unfold, insert in the membrane, and recruit more C9 until a rigid ring structure, the classical MAC, has assembled (Podack and Tschopp 1984). The MAC ring, comprising between 12 and 18 C9 molecules, surrounds a pore through which ions and water can pass, causing osmotic lysis of the target. It should be noted that complete rings, the hallmark of the MAC, are not essential for this lytic process; even complexes containing as few as two or three C9 molecules cause considerable bilayer disruption, generating functional pores.

The active products of C

The physiological roles of C are mediated by the products of the pathways described above. In the activation pathways, the small fragments of C3 and C5 shed upon enzymatic cleavage, C3a and C5a, are powerful cell activators whereas the large fragments of C3 and C4 bound to the activating surface, C3b and C4b, direct phagocyte attack. The MAC can cause direct lysis of targets but may also trigger activation events in cells.

The opsonic C fragments

During C activation, pathogens become coated with C3b, C4b, and their breakdown products, a process termed 'opsonization'. These large fragments bind specific C receptors on phagocytes, triggering internalization and destruction of the pathogen. The important phagocyte receptors are C receptor 1 (CR1, CD35), which binds C3b and C4b, and CR3 (CD11b/CD18) and CR4 (CD11c/CD18) which both bind inactivated C3b (iC3b) (Krych et al. 1992). CR1 is a member of the regulators of C activation (RCA) family and, indeed, also functions as a C regulator (see below) (Rey-Campos et al. 1990). CR3 and CR4 are members of the integrin family of cell surface receptors (Myones et al. 1988). C3 fragments iC3b and C3d also bind another receptor, CR2 (CD21), an RCA family member structurally related to CR1 (Krych et al. 1992). CR2, absent on phagocytes but expressed on B cells, some T cells, follicular dendritic cells, and a few other cell types, plays

important roles in the response to antigen, described below, under Role of C in the adaptive immune response. CR1 is also expressed on erythrocytes where it plays an important role in the transport of immune complexes (Madi et al. 1991; Pascual and Schifferli 1992). Immune complexes, coated with C3b through classical pathway activation, bind to CR1 on the erythrocyte, effectively removing the immune complex from the circulation – the immune adherence phenomenon. Immune complexes are stripped from erythrocytes passing through the spleen and liver and transferred to fixed macrophages, expressing C receptors and antibody Fc receptors, which endocytose and destroy the complex. The mechanism by which the immune complex is released from erythrocyte CR1 and the fate of CR1 during this process of immune complex stripping are still the subject of debate. Early studies suggested that CR1 was cleaved from the erythrocyte and lost during delivery; indeed, the reduced expression of CR1 on erythrocytes in systemic lupus erythematosus (SLE) was ascribed to this process (Davies et al. 1990, 1992). However, others showed that there was little or no loss of CR1 during passage of immune complex-loaded erythrocytes through the spleen and proposed a dynamic binding model for erythrocyte transport of immune complexes (Schifferli and Peters 1983; Schifferli and Taylor 1989). C3b attached to CR1, a cofactor for fI, is rapidly cleaved to iC3b, thereby releasing the attachment, only for another C3b to take up the attachment. In the spleen, macrophages expressing multiple C receptors and Fc receptors compete to capture the immune complex without loss of erythrocyte CR1. To complicate things still further, more recent elegant studies of immune complex handling in nonhuman primates clearly show that proteolysis of CR1 occurs together with delivery of the immune complex, brought about by specific proteases on the macrophage surface after the immune complex-laden erythrocyte has been captured through macrophage Fc receptors (Nardin et al. 1999).

The anaphylactic and chemotactic C peptides

Several active fragments are released into the fluid phase during C activation. C3a and C5a are structurally similar peptides (77 and 74 amino acids, respectively) released by the convertases of the activation pathways that mediate biological effects through distinct cell receptors, the C3a receptor (C3aR) and C5a receptor (C5aR, CD88) (Hugli 1984; Gerard and Gerard 1994; Ames et al. 1996). These are both members of the large family of seven-transmembrane, G-protein-coupled receptors and signal upon binding their respective ligands. C5a is arguably the most biologically active of the activation products. Binding of C5a to its receptor on neutrophils and other phagocytes triggers cell activation, chemotaxis towards the source, generation of reactive oxygen species, release of toxic cytoplasmic granule contents (enzymes, histamine, leukotrienes, etc.), and upregulation of adhesion properties. The net result is the recruitment of 'angry phagocytes' to the site of complement activation. C5aR is expressed on numerous other cell types, including astrocytes, smooth muscle cells, and endothelia, but the effects of C5a on these cells are still unclear. C3aR is also expressed on phagocytes – in high number on eosinophils and basophils, but in very low number on neutrophils (Zwirner et al. 1999). Binding of C3a activates cells abundantly expressing C3aR, but has little or no role in neutrophil activation. As with C5a, the effects of C3a on the many other cell types that express the receptor are unclear. The effects of C3a and C5a are focally and temporally limited because they are rapidly inactivated by a plasma enzyme termed carboxypeptidase N (anaphylatoxin inactivator). This enzyme cleaves the carboxy-terminal arginine (Arg) to generate the 'desArg' forms (C3a-desArg, C5a-desArg), thereby completely inactivating C3a and reducing the activity of C5a by one or two logs.

An intriguing story has emerged over the last decade linking C3a-desArg with the regulation of fat metabolism (Cianflone et al. 1994). The story began with the identification of a plasma protein, termed acylation stimulating protein (ASP), which stimulated triglyceride synthesis in fibroblasts and adipocytes in vitro. Characterization of purified ASP revealed that it was identical to C3a-desArg! This, together with the demonstration that adipose tissue was a major site of synthesis of fD (originally termed 'adipsin' in this context) and also produced C3 and fB, led to the proposal that a novel pathway involving local alternative pathway activation in adipose tissue to produce C3a-desArg (ASP) was a major homeostatic factor for fat metabolism (Sniderman and Cianflone 1997). In support of this proposal, a putative receptor for C3a-desArg was demonstrated on adipocytes. Doubt has been cast on the central role of this 'adipsin-ASP' pathway in fat metabolism, perhaps most persuasively from those who point out that C3 deficiency in humans and mice is not associated with deficits in lipid metabolism (Kildsgaard et al. 1999).

Of the other fragments and complexes generated during activation, the C4a fragment, although structurally related to C3a and C5a, does not appear to have any biological role in humans. The fragment Ba released during alternative pathway activation has been implicated as an immunosuppressive agent, but the evidence is weak and the mechanisms undefined (Oppermann et al. 1991). The fluid-phase product of terminal pathway activation, SC5b-9 (also called terminal C complex (TCC)), has been shown to activate both neutrophils and endothelia, although no receptor for this complex has yet been identified (Tedesco et al. 1997; Dobrina et al. 2002).

Role of C in the adaptive immune response

The activities described above, opsonization of immune complexes and pathogens, chemotactic attraction and activation of phagocytes, and other cell activation events, can be considered as the 'classical' consequences of C activation, acting to dispose of pathogens and other toxic entities. It is now apparent that there are other, less well-defined but equally important roles of C activation that contribute to homeostasis and the immune response.

A role for C in the adaptive immune response to antigen was first suggested by Pepys in a landmark paper in 1974. Pepys (1974) showed that the antibody response to T-cell-dependent antigens was severely blunted in C-depleted mice, implying a role for C in the immune response to antigen. The mechanism underlying this seminal and controversial finding was not identified until the early 1990s when Tedder, Fearon, and co-workers identified a critical role for CR2 (Tedder et al. 1986; Matsumoto et al. 1991; Fearon 1991). They showed that CR2 expressed on B cells is present in a complex with CD19 and other signaling molecules and plays a key role in the B-cell response to antigen (Figure 4). Particulate antigens coated with C3d, the cell-bound end-product of C3b inactivation, will bind both through the B-cell receptor and through CR2, delivering additional stimuli to the B cell and lowering the threshold of cell response to antigen by several orders of magnitude (Tedder et al. 1997; Fearon and Carroll 2000). CR2 on follicular dendritic cells plays a similar, though less well-defined, role and appears to be required for efficient antigen trapping. This key role of C3d in the generation of an efficient immune response is now being exploited in immunization studies where C3d coupled to antigen acts as a molecular adjuvant (Dempsey et al. 1996). C thus provides a strong link between the innate and adaptive immune systems that had previously been considered primarily as discrete, non-interacting systems.

Role of C in apoptosis

Cell death follows one of two pathways: either necrosis involving disruption of the plasma membrane by an external agent and release of intracellular contents, or apoptosis involving the triggering of an endogenous cell death program that leaves the plasma membrane intact and does not release cell contents. Given the lytic capacity of the MAC, a role for C in necrosis is easy to envi-

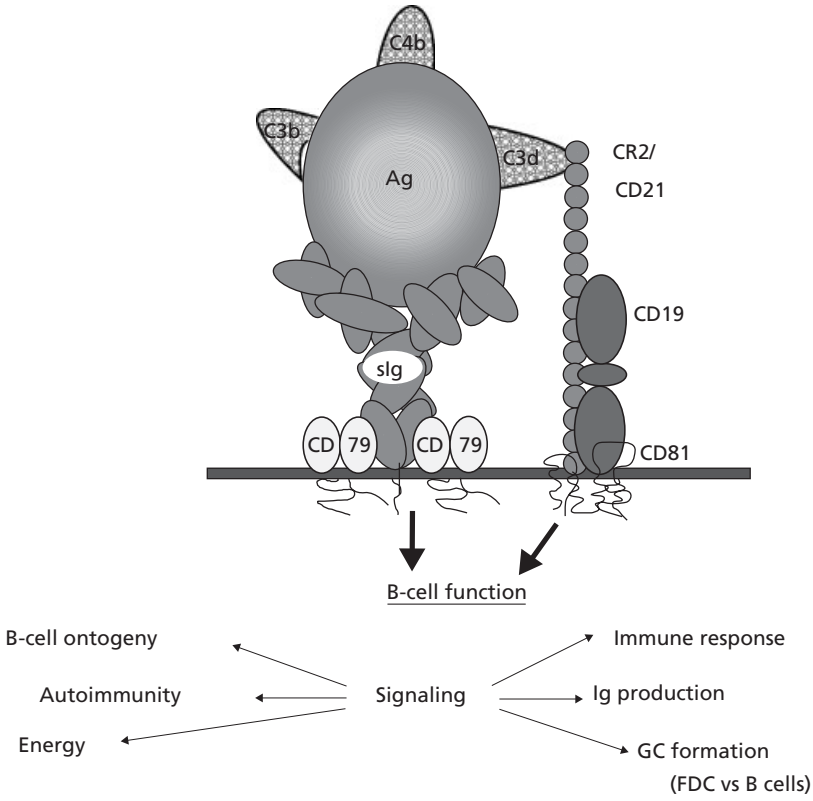

Figure 4 *The role of C in the B-cell response to antigen. The antigen (Ag) or immune complex becomes coated with C3b and other C fragments. Enzymatic degradation of C3b leaves C3d fragments, the ligand for CR2, attached to the activating complex. When antigen binds the specific B-cell membrane receptor (slg), CR2 together with its associated molecules (CD19, CD81) is recruited through binding of C3d. The net result is that signals are transmitted to the B cell both through the B-cell receptor complex and through the CR2/CD19/CD81 complex, thereby lowering the threshold for B-cell response to antigen.*

sage. Indeed, in numerous models of ischemic injury where necrotic cell death is predominant, an important role for C, and specifically the MAC, has been demonstrated (see section on Complement in specific pathologies). Necrotic cell debris triggers further inflammation and C activation, in part through binding of the C activator, CRP, to the cell debris (Griselli et al. 1999). This in turn exacerbates injury in the models. Apoptosis, in contrast, is a 'clean' process that does not involve the release of cell contents and is not proinflammatory. Apoptotic cells will eventually undergo necrotic changes, making efficient removal by phagocytes an essential part of the process. Although C opsonization is an excellent means of targeting phagocytosis, it is somewhat counterintuitive to suggest that the proinflammatory C system might be involved in apoptosis. Indeed, numerous non-C recognition and uptake systems have been identified for the safe removal of apoptotic cells (Savill et al. 1993; Savill and Fadok 2000). Nevertheless, there is abundant evidence from in vitro studies that cells undergoing apoptosis activate C and are opsonized for uptake by phagocytes using the opsonic C receptors described above (Navratil and Ahearn 2001; Mold and Morris 2001). The relevance of opsonization to removal of apoptotic cells in vivo is a continuing source of controversy and the activating triggers a source of debate (Medzhitov and Janeway 2002). Early studies indicated that apoptotic cells activated the alternative pathway (Matsui et al. 1994), whereas later work demonstrated binding of C1q and MBL to sites on the apoptotic blebs, implicating the classical and lectin pathways (Navratil et al. 1999, 2001; Mevorach 2000; Ogden et al. 2001). Whatever the activating pathway, the consequences of C activation will be the same. Opsonization may aid clearance but, if activation were to proceed through to MAC formation, then lysis would ensue with unwanted inflammatory consequences. It has been suggested that activation of the terminal pathway on apoptotic cells is restricted, although no mechanism has yet emerged (Gershov et al. 2000).

Further evidence implicating the classical pathway in apoptotic cell clearance came from analysis of mice deficient in C1q. The mice developed an autoimmune glomerulonephritis with an accumulation of apoptotic cells in the kidney, apparently caused by defective clearance (Botto et al. 1998). These symptoms closely resembled those seen in C-deficient individuals with SLE or lupus-like disease, and provided a new concept of how C deficiency causes SLE, defects in clearance of apoptotic cells rather than immune complexes being key (Taylor et al. 2000). Perhaps the best analogy for the role of C, and specifically the classical pathway, in the prevention of SLE is that suggested by Walport (2001a), the 'waste disposal' hypothesis. This suggests that activation of C on immune complexes, apoptotic cells, and perhaps other debris labels these items as garbage for rapid and efficient clearance by phagocytes. Failure of this system, because of either C deficiencies or a garbage load that exceeds the labeling capacity of the system, will lead to the accumulation of garbage with resultant disease.

C activation products have also been implicated as modulators of apoptosis. C5a has been shown to protect neutrophils from apoptosis (Lee et al. 1993; Perianayagam et al. 2002), but accelerate apoptosis in thymocytes (Guo et al. 2000; Riedemann et al. 2002). In neurons, different studies have reported C5a-induced protection from (Mukherjee and Pasinetti 2001) or induction of (Farkas et al. 1998) apoptosis. The MAC can also influence apoptosis. Using C6-deficient rats in models of renal disease, the MAC was shown to drive apoptosis of mesangial and endothelial cells (Sato et al. 1999; Hughes et al. 2000). In contrast, exposure to nonlethal MAC attack of Schwann cells and oligodendrocytes, the myelin-producing cells of the peripheral and central nervous systems, respectively, protected against apoptosis (Dashiell et al. 2000; Soane et al. 2001). The overall picture is one of confusion, with different cell types responding in dramatically differing ways, the only common thread being that C activation products exert an influence, positive or negative, on the apoptotic process.

REGULATION OF C

It is evident from the above description of the active products that the C system carries with it the potential to harm self, hence the much-repeated adage that C is a 'double-edged sword'. To minimize damage to self, C is tightly controlled at multiple stages in the pathway by regulatory proteins present in plasma and on cell membranes (Table 2 and Figure 5) (Morgan and Harris 1999).

Regulation in the activation pathways

The first step of the classical pathway is regulated by C1-inhibitor (C1inh), a serine protease inhibitor (serpin), present in plasma at about 150 μg/ml. C1inh binds activated C1 and removes C1r and C1s from the complex (Davis 1988, 1989). C1inh forms a covalent complex comprising two molecules of C1inh and one each of the target proteases C1r and C1s ($C1inh_2C1rC1s$), and is itself cleaved in the process, therefore acting as a suicide pseudosubstrate inhibitor. C1inh is the only plasma inhibitor of activated C1 but also regulates kallikrein in the contact activation system of kinin generation and factors XIa and XIIa in the coagulation system. C1inh may also act to stabilize the proenzymic C1 complex by binding C1 in plasma, thereby reducing the likelihood of activation (Ziccardi 1982).

Although still a matter of debate, the weight of evidence indicates that C1inh also regulates the initial step in the lectin pathway (Matsushita et al. 2000). Regulation by C1inh mirrors that described for C1, acting to remove the proteases MASP-1 and MASP-2

Table 2 *The regulatory proteins of the C system*

Regulator	Structure/function	Plasma concn/tissue distribution
Activation pathways		
C1inh	Single chain, two-domain heavily glycosylated, approx. M_r 104 kDa. Suicide inhibitor of activated C1	150 μg/ml (approx. 2 μmol/l)
fH	Single chain, 20 SCRs, approx. M_r 155 kDa; cofactor and decay accelerator for AP convertases	550 μg/ml (approx. 3.5 μmol/l)
fHL-1	Single chain, 7 SCRs, approx. M_r 42 kDa, cofactor and decay accelerator for AP convertases, adhesion	30 μg/ml (approx. 0.7 μmol/l)
C4BP	Oligomer comprising 7 α chains (8 SCRs) and 1 β chain (3 SCRs), approx. M_r 550 kDa. Cofactor and decay accelerator for CP convertases	250 μg/ml (approx. 0.45 μM)
fI	Two-chain from single chain precursor, serine protease, approx. M_r 90 kDa. Cleavage of C3b/C4b in convertases	35 μg/ml (approx. 0.40 μmol/l)
DAF	Single chain, 4 SCRs, GPI tail, approx. M_r kDa. Decay of CP and AP convertases	Broadly distributed, all blood cells, endothelia. Soluble DAF in plasma
MCP	Single chain, 4 SCRs, tm tail, approx. M_r 60 kDa (two major isoforms), cofactor for CP and AP convertases	Broadly distributed, not on human E
Terminal pathway		
S-protein	Single chain, 75 kDa, binds C5b-7 complex and prevents membrane insertion	350 μg/ml (approx. 4.5 μmol/l)
Clusterin	Two chains (α and β each approx. 40 kDa) from single chain precursor. Binds C5b-7 complex and prevents membrane insertion	200 μg/ml (approx. 3 μmol/l)
CD59	Single chain, compact, globular, GPI tail, approx. M_r 20 kDa, heavily glycosylated. Inhibits MAC assemby	Broadly distributed, all blood cells, endothelia, etc.

from the activated MBL–MASP complex. C1inh forms covalent complexes with the MASPs, although the precise stoichiometry of these complexes is uncertain (Petersen et al. 2000). Regulation of MBL–MASP

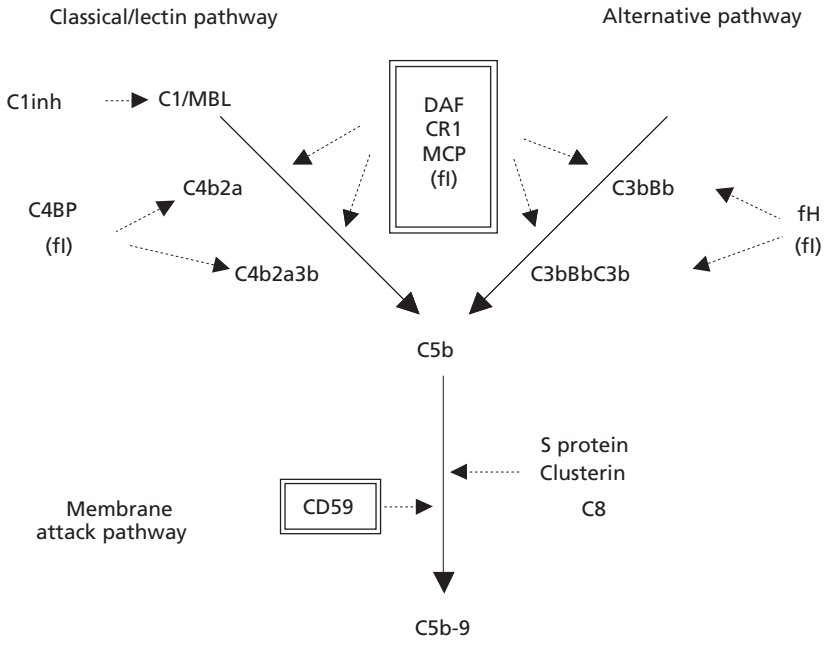

Figure 5 *C regulators. The fluid-phase and membrane regulators of C are illustrated, with broken arrows indicating the points in the pathway at which they exert their effects. Membrane regulators are boxed. Abbreviations as in the text.*

activity by α_2-macroglobulin, a plasma protease inhibitor structurally related to C3/C4, has also been reported in vitro, and complexes of MBL–MASP with α_2-macroglobulin have been detected in plasma (Terai et al. 1995). The physiological relevance of this interaction is unknown.

Control of the C3 and C5 convertases is provided by fI, a highly specific serine protease, which, in the presence of essential cofactors, cleaves the α chains of C3b and C4b to inactivate the convertases (DiScipio 1992b). In plasma, two proteins act as cofactors for fI, factor H (fH) in the alternative pathway and C4-binding protein (C4BP) in the classical pathway (Dahlback 1983). Both fH and C4BP also inhibit by accelerating the decay of the convertases. fH is the index member of a large family of structurally related proteins (Zipfel et al. 1999). One of these, fH-like-1 (fHL-1) arises by alternative splicing in the *fH* gene and regulates C. The others, fH-related proteins 1–5 (fHR-1 to fHR-5) are encoded by linked genes in the RCA cluster; their function is still under study.

On the membrane, decay accelerating factor (DAF) (CD55) acts to accelerate the decay of convertases, whereas membrane cofactor protein (MCP, CD46) acts as cofactor for the cleavage of C4b and C3b by fI, irreversibly inactivating the enzyme (Lublin and Atkinson 1990). Both are widely distributed, present on most cell types, although MCP is conspicuously absent from erythrocytes in humans. CR1, a large transmembrane protein mentioned above as a C fragment receptor, is also a regulator of C with both decay accelerating and cofactor activities (Holers et al. 1986). It is expressed on erythrocytes, B cells, polymorphonuclear leukocytes, follicular dendritic cells, and several other cell types. The active sites for C regulation in CR1 are placed a considerable distance from the membrane in the large CR1 molecule, provoking the suggestion that CR1 acts extrinsically to regulate C activation on surrounding cells and surfaces.

With the exception of fI, all of the regulators of C3/C5 convertases and several of the receptors for fragments of C3, C4, and C5 are members of a gene family, called the RCA family, encoded in the RCA locus on chromosome 1q32 (Hourcade et al. 1989). All contain multiple copies of a conserved structural unit, the short consensus repeat (SCR), comprising a compact motif of 60 amino acids with conserved disulfide bridges. Some RCA proteins, such as fH, are made up entirely of SCR units, whereas others contain additional domains performing other roles. The SCR unit is also found in non-RCA molecules that interact with C3, C4, or C5, including the C proteins C1r, C1s, C2, fB, C6, and C7.

Control in the membrane attack pathway

The membrane attack pathway is also regulated by inhibitors present in the fluid phase and on membranes. The fluid-phase C5b-7 complex is the target of S-protein (vitronectin) and clusterin, abundant plasma proteins (each about 0.2–0.5 mg/ml) that, among their many other roles, help regulate C activation by binding the hydrophobic site in C5b-7 and preventing its association with membranes (Podack and Muller-Eberhard 1979; Tschopp and French 1994). Binding of C8 to the fluid-phase C5b-7 complex also blocks attachment to the membrane. On the membrane, CD59, a small, compact, glycolipid-anchored membrane protein unrelated to the RCA-encoded regulators, binds tightly to C8 in the C5b-8 complex and perhaps also to C9 in the C5b-9_1 complex, thereby blocking further incorporation of C9 and assembly of the MAC (Lachmann 1991; Morgan 1999).

COMPLEMENT DEFICIENCIES

Deficiencies of almost every C protein and regulator have been described, giving a wide range of signs and symptoms, depending on the pathways affected by the deficiency (Figure 6). These 'experiments of nature' give important information on the physiological roles of C and have pointed the way to some surprising discoveries.

Classical pathway deficiencies

Deficiencies of components of the classical pathway (C1, C4, or C2) are strongly associated with a syndrome clinically indistinguishable from SLE, a consequence of the failure of immune complex solubilization (Walport and Lachmann 1990). The frequency and severity of disease are greatest with deficiencies of one of the subunits of C1 (C1q, C1r, C1s), closely followed by total C4 deficiency (Kolble and Reid 1993). The incidence of SLE is almost 100 percent in C1q deficient subjects, close to 70 percent in those deficient in C1r and/or C1s, and 75 percent in total C4 deficiency. C4 is unusual in that it is encoded by duplicated genes differing in only a few amino acids but yielding proteins (C4A and C4B) that are functionally distinct (Schifferli and Paccaud 1989). As a result of the presence of four loci, complete deficiency of C4 is exceedingly rare, but null alleles at one or more of the four C4 loci are common, giving rise to partial or complete deficiencies of either C4A or C4B. Deficiencies of each isotype have been associated with an increased incidence of lupus-like disease, bacterial infection, and numerous other disorders. Deficiency of C2 is the most common homozygous C deficiency in white people but infrequently causes disease – most C2 deficiencies have been identified by chance in healthy individuals. About 10 percent of C2-deficient individuals present with SLE. The strong association of immune complex disease with classical pathway deficiencies is a consequence of the failure of the 'waste

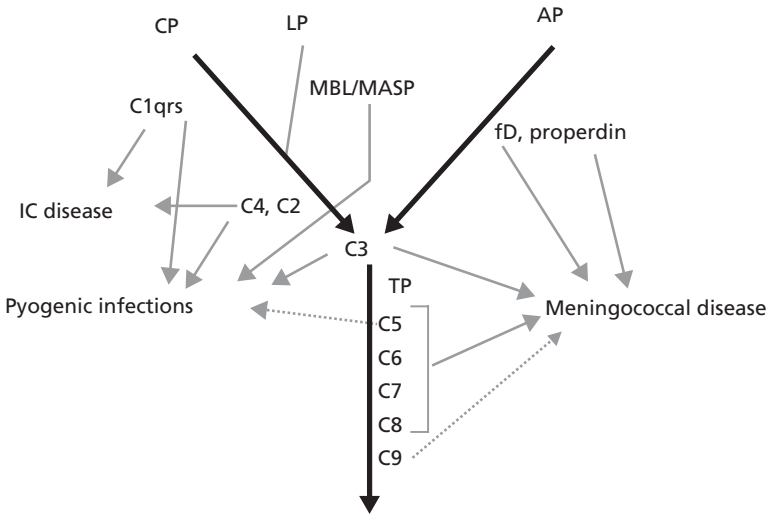

Figure 6 *C deficiencies. The clinical sequelae of deficiencies in different parts of the C system are summarized. AP, alternative pathway; CP, clasical pathway; IC, immune complex; LP, lectin pathway; other abbreviations as in the text.*

disposal' role of the classical pathway described in earlier. Bacterial infections are not usually a prominent feature of deficiencies in the classical pathway, illustrating the dominant role of the alternative pathway in dealing with bacteria.

Alternative pathway deficiencies

Deficiencies of alternative pathway components are rare. A few individuals deficient in fD have been described, all of whom have presented with severe and/or recurrent neisseria infections, usually meningococcal meningitis (Biesma et al. 2001). Homozygous deficiency of fB has not been reported, leading to the assumption that the defect was lethal. However, the mild phenotype observed in fB-deficient mice indicates that survival is possible in the absence of fB (Matsumoto et al. 1997).

Deficiency of the positive regulator, properdin, is the most common disorder of the alternative pathway and is also associated with meningococcal infection (Sjoholm et al. 1982). Properdin is encoded on the short arm of the X-chromosome and deficiencies are therefore found only in males. Three distinct forms of the deficiency have been described: type 1, the most common, is associated with complete absence of the protein, type 2 with low levels (1–10 percent) of apparently active protein, and type 3 with normal levels of a functionally impaired protein (Sjoholm et al. 1988a, b; Fijen et al. 1999). Affected individuals usually present with fulminant meningococcal disease that is frequently fatal. Disease onset occurs later than is usual for meningococcal disease (average age of onset 14 years) and is frequently caused by unusual serotypes of the meningococcus. Survivors rarely get recurrence because the antibody response developed during first infection is protective. Screening of male siblings is essential when properdin deficiency is identified because immunization can forestall the risk of a potentially fatal outcome.

Lectin pathway deficiencies

Defects in the lectin pathway are surprisingly common. Indeed, discovery of the pathway followed analyses in a cohort of infants presenting with recurrent bacterial infections. These infants exhibited a reduced capacity of their serum to opsonize yeast particles with C3b, initially ascribed to a defect in the alternative pathway (Soothill and Harvey 1976, 1977). Population screens identified this opsonic defect in up to 5 percent of the population, the large majority of whom had no history of recurrent infections. On closer analysis, no specific alternative pathway deficiency was identified in these individuals. More than a decade later, an association of the opsonic defect with a deficiency of MBL, the C1q-like lectin that is the recognition unit of the lectin pathway, was demonstrated (Super et al. 1989; Turner 1991). About 5 percent of the population in northern Europe have little or no MBL in plasma; in almost all cases, one of three point mutations in the *mbl* gene is present, each causing a single amino acid substitution in the collagen-like domain (Lipscombe et al. 1996; Summerfield et al. 1997). These substitutions interfere with the oligomerization of MBL monomers into the functional protein. Plasma levels in homozygotes are essentially zero, whereas, in heterozygotes, plasma levels vary from about 10 to 50 percent of normal, depending on the polymorphism, although functional activity may be much lower because oligomers containing mutant chains are functionally impaired. Clinical sequelae of MBL deficiency were initially considered to be restricted to infants; however, recent studies have demonstrated that MBL deficiency is also a risk factor for infection in

immunodeficient adults and may be associated with increased disease severity in autoimmunity (Sumiya and Summerfield 1996; Petersen et al. 2001).

Inherited and acquired deficiencies of C3

C3 is the lynchpin of the C system, an essential component of all activation pathways and vital for efficient opsonization of bacteria. Deficiency is associated with a marked susceptibility to bacterial infections and, because of the critical role of C3 fragments in responses to antigen, a generalized reduction in immune responsiveness (Botto and Walport 1993). Some C3-deficient individuals also develop glomerulonephritis or lupus-like illness as a result of defects in immune complex handling. Skin rashes are a frequent feature, particularly during infective episodes. The large majority of C3-deficient individuals present with severe, recurrent infections early in life that can be fatal. However, prophylactic antibiotic therapy can now rescue such individuals, enabling survival into adulthood.

Secondary deficiencies of C3 resulting from consumption can also occur. C3 consumption associated with deficiencies of C regulators is discussed below; here, other factors that cause pathological consumption of C3 are introduced. Perhaps the most clinically relevant are autoantibodies, termed C3 nephritic factors (C3NeF), which bind and stabilize the C3 convertase of the alternative pathway, C3bBb (Walport et al. 1994). C3NeFs usually occur in the absence of other features of autoimmunity and the underlying trigger for their production is unknown. Although C3 is consumed systemically and plasma C3 levels can be very low, the dominant clinical consequence is membranoproliferative glomerulonephritis. Less commonly, C3NeFs cause an unusual and distressing syndrome, partial lipodystrophy, in which near-total fat loss occurs, predominantly in the upper body (Mathieson et al. 1993). Adipose tissue is targeted because it is the major site of synthesis of fD in the body. C3bBb complexes can thus form readily in the tissue and, in the presence of a C3NeFs, these complexes are stabilized and cause local activation of C sufficient to kill adipocytes. The gradient of fat loss, with the face and upper extremities most affected, reflects a differential capacity of adipose tissue to produce fD (Mathieson et al. 1993). Rarely, autoantibodies that bind and stabilize the classical pathway convertase C4b2a, C4 nephritic factors (C4NeF), occur; like C3NeFs, these consume C3 and are associated with glomerulonephritis and also lupus-like pathology (Daha et al. 1976).

Terminal pathway deficiencies

Deficiencies of terminal pathway components (C5, C6, C7, C8, or C9) cause susceptibility to infection with organisms of the genus *Neisseria* – meningococcal meningitis and systemic infection with the meningococcus (Wurzner et al. 1992). This reflects the role that the MAC plays in bactericidal activity against this group of organisms. It should, however, be stressed that most individuals with terminal pathway deficiencies remain healthy and are ascertained by chance. Deficiency of C5 causes loss not only of MAC function but also of the potent chemotactic and cell-activating fragment C5a. Despite this, the spectrum of disease in C5-deficient individuals does not differ from that in deficiencies of other terminal components. C6 deficiency is the second most common C deficiency in caucasians; other terminal pathway deficiencies are rare in this group. Deficiency of C9 deserves special mention for three reasons: first, because the link with meningococcal disease, although still present, is weaker, probably because C9-deficient serum kills bacteria, albeit inefficiently (Pramoonjago et al. 1992). Second, because it is extremely common in Japan where 0.1 percent of the population are deficient in C9. Virtually all Japanese C9-deficient individuals carry the same defect, a stop mutation early in the coding region (D^{95}→Stop) (Horiuchi et al. 1998). Almost 7 percent of the Japanese population are carriers for this mutation. Third, the C9 concentration in neonates is extremely low, reaching adult levels a few months after birth (Lassiter et al. 1992; Hogasen et al. 2000). Neonates are thus likely to have reduced capacity to form MAC and may as a consequence be more susceptible to infection with *Neisseria* spp.

Deficiencies of C regulators

The activation pathways are regulated from the fluid phase by the serpin C1inh and by the enzyme fI, together with its cofactors, fH in the alternative pathway and C4BP in the classical pathway. Deficiency of C1inh deserves particular attention because it causes a syndrome termed hereditary angioedema (HAE), a relatively common, distressing and potentially lethal disorder characterized by episodic painless swelling of areas of the skin or mucosa (Carugati et al. 2001). Involvement of the laryngeal mucosa can cause asphyxia and gut involvement may mimic an acute abdominal emergency. HAE is unusual in that symptoms manifest in individuals heterozygous for defects in the C1inh gene. C1inh is the sole plasma regulator of activated C1 and also regulates activation in the contact and coagulation systems. Because C1inh is a 'suicide inhibitor', consumed when it interacts with its enzyme target, plasma levels reflect a balance between ongoing consumption and biosynthesis. A decreased rate of biosynthesis in the face of sustained consumption will therefore rapidly result in very low plasma levels of C1inh. In heterozygotes, synthesis will be reduced by around 50 percent but plasma levels of C1inh may be 10

percent or less. Attacks often follow minor trauma that initiates activation of the C and contact systems, normally held in check by C1inh. The products of uncontrolled activation, particularly bradykinin and fragments of C2, cause local increased vascular permeability that underlies the tissue edema. HAE affects about 1 in 50 000 people (Davis 1988); more than 20 percent of cases are the result of new mutations and therefore lack a family history of disease (Agostoni and Cicardi 1992). The most common form of HAE, type 1, involves mutations in the C1inh gene that yield little or no protein. Measurement of C1inh protein and function correlate and are both low. In some 15 percent of cases the mutated gene yields an abnormal, functionally compromised protein usually resulting from point mutations that cause amino acid substitutions at or near the active site of the enzyme (Davis et al. 1993). The abnormal protein is detected in antigenic assays, giving normal or elevated serum concentrations and masking the deficiency (type 2 HAE). Functional assays are essential to make the diagnosis. Angioedema indistinguishable from that in HAE may also occur in older individuals, usually in association with lymphoproliferative disease and, occasionally, other malignancies (Cicardi et al. 1996). Here, low level activation of the classical pathway by the large tumor mass and resultant consumption of C1inh causes a secondary deficiency (acquired angioedema (AAE)). Rarely, AAE may occur, in the absence of malignancy, caused by the presence of blocking autoantibodies against C1inh (Mandle et al. 1994).

The factors fI and fH collaborate to control the alternative pathway convertases in the fluid phase and on surfaces. In the absence of either, control fails causing unregulated activation of C and consumption of C3 and other components. Individuals deficient in fI or fH thus have profound secondary deficiency of C3 and the clinical consequences are essentially identical to those described for C3 deficiency. Individuals deficient in fH often have, in addition, renal disease, most commonly membranoproliferative glomerulonephritis or the hemolytic uremic syndrome (HUS). The association of idiopathic (noninfectious) HUS with fH deficiency is of particular interest. Although the link was first noted in patients with low plasma levels of fH, it has now become clear that apparently trivial mutations in the carboxy-terminal region of fH, which have little effect on the plasma level of the protein, can cause HUS, perhaps by interfering with the capacity of fH to bind surfaces (Taylor 2001; Zipfel 2001).

Deficiency of C4BP is rare and the few reports in the literature are lacking in information. Various autoimmune-like symptoms and angioedema have been seen in individuals with complete or partial deficiencies of C4BP but no clear evidence of causative association has emerged.

On membranes, DAF and MCP, the latter as a cofactor for fI, control the activation pathway convertases. No reports of MCP deficiency exist in the literature. DAF deficiency can occur as a global absence of DAF as a result of mutations in the *Daf* gene, or absence from circulating cells in the syndrome paroxysmal nocturnal hemoglobinuria (PNH), secondary to defects in glycosyl phosphatidylinositol (GPI) anchor synthesis. In PNH, erythrocytes and other circulating cells arising from the mutant hemopoietic stem cell clone lack all GPI-anchored proteins on the membranes (Rosse and Ware 1995). The absence of the C regulators DAF and CD59 renders the cells susceptible to C damage in the circulation, causing hemolysis, thrombosis, and leukocyte activation. Erythrocytes are particularly affected because they naturally lack MCP and are thus essentially devoid of protection from C. Several DAF-deficient individuals have been described, recognized because of the absence of the Cromer blood group antigens (the *Inab* phenotype), known to reside within DAF (Merry et al. 1989; Telen and Green 1989). Individuals deficient in DAF were healthy apart from a vague association with intestinal problems in some families. In particular, DAF-deficient individuals did not have intravascular hemolysis or other evidence of C damage to circulating cells.

No reports of complete deficiencies of S-protein (vitronectin) or clusterin, the fluid-phase inhibitors of the terminal pathway, have been published. These proteins have numerous biological roles outside the C system that probably make them indispensable. On the membrane, CD59 regulates the terminal pathway (Davies and Lachmann 1993). As noted above, PNH cells are deficient in CD59 and DAF as a result of defective GPI anchor synthesis and are, as a consequence, susceptible to C damage. A single individual with global absence of CD59 caused by *Cd59* gene mutation has been reported, presenting at a young age with symptoms compatible with PNH (Yamashina et al. 1990). Taken together with the lack of symptoms associated with DAF deficiency, these observations make it clear that CD59 is crucial for survival of cells in the circulation.

COMPLEMENT IN SPECIFIC PATHOLOGIES

Inappropriate activation of C occurs in a large number of inflammatory, iatrogenic, ischemic, and other diseases and, in many, is a major contributor to the initiation or perpetuation of tissue damage (Table 3). Pathological effects are mediated by precisely the same mediators that are responsible for the protective roles of C described above. The anaphylactic and chemotactic peptide C5a drives inflammation by recruiting and activating neutrophils, C3a may cause pathological activation of other phagocytes, the MAC may kill or injure cells, and so on. Evidence for a role of C may be sought in humans by looking for the products of C activation either in the tissues or in plasma. In many cases, animal

Table 3 *Examples of diseases in which C is implicated*

Disease	Evidence of C involvement
Immune-mediated diseases	
Rheumatoid arthritis (RA)	Consumption of plasma C in acute disease; C activation products in synovial fluid and synovial membrane; C inhibition (various agents) suppresses disease in animal models of rheumatoid arthritis (RA); C deficiency suppresses disease in mouse models of RA
Membranoproliferative glomerulonephritis (MPGN)	Abundant deposits of C activation products, including membrane attack complex (MAC), in glomeruli; C inhibition (various agents) suppresses disease in models of MPGN; intrarenal administration of C regulators suppresses disease in models
Multiple sclerosis (MS)	C activation products in CSF and around areas of demyelination in the CNS; C inhibition (various agents) suppresses disease in animal models of MS; C deficiency suppresses disease in rodent models of MS
Myasthenia gravis (MG)	Abundant C activation products at motor end plate during attacks; C deficiency or depletion abrogates disease in rodent models; C inhibition (CVF; sCR1) suppresses disease in models of MG
Degenerative diseases	
Alzheimer's disease	C activation products in and around plaques in CNS; anti-inflammatory therapy appears to slow progression
Ischaemia–reperfusion injuries	
Myocardial infarct (MI)	Reperfusion associated with C activation in ischemic area; abundant deposits of C activation products in and around infarct; C inhibition at time of reperfusion in models reduces size of infarct
Stroke	Evidence as described above for MI

For references, see the text.

models have proved invaluable in dissecting the roles of C in diseases. Here, no attempt is made to discuss all of these diseases but instead a few examples of disease groups where C plays a part are given.

Complement in SLE and related syndromes

Systemic lupus erythematosus (SLE) is characterized pathologically by the presence of immune complex deposits in affected tissues such as the kidney and skin, which are invariably associated with deposition of C components. Plasma C activity and plasma levels of specific components, particularly C3 and C4, are low in severe disease, reflecting the massive C consumption that occurs in the tissues. These observations have generated the consensus view that C activation drives tissue damage in SLE and related diseases. However, this consensus is difficult to reconcile with the knowledge that disease closely resembling SLE occurs in individuals deficient in components of the classical pathway, where the capacity to generate the toxic products of C activation will be impaired (Navratil et al. 1999). A better explanation for the occurrence of SLE in C-deficient and C-sufficient individuals is provided by Walport's 'waste disposal' hypothesis (Walport 2001b). This suggests that a crucial role of C is the safe disposal of immune complexes and apoptotic cells via binding of C1 and C4 and subsequent engulfment by macrophages. In C deficiency the process fails because of a global lack of these components. In idiopathic SLE it fails because consumption of C causes a localized, secondary deficiency of C1 and C4. In either situation, accumulation of 'garbage' in the tissues is toxic and initiates further tissue damage.

An additional precipitating factor in some individuals with idiopathic SLE is the presence of autoantibodies against the collagen-like region (CLR) of C1q (anti-C1q CLR), which are thought to affect C1 function (Strife et al. 1989; Wener et al. 1989). The presence of anti-C1q CLR antibodies correlates strongly with the severity of renal disease in SLE. These autoantibodies are also found in association with several other pathologies, including membranous glomerulonephritis, rheumatoid vasculitis, and hypocomplementemic urticarial vasculitis (HUVS). Virtually all patients with HUVS have anti-C1q CLR antibodies and the presence of these antibodies has been used as a diagnostic test for this syndrome (Wisnieski and Naff 1989; Wisnieski et al. 1995).

Complement in ischemia–reperfusion injuries

Many common conditions are caused by a transient or permanent loss of blood supply to tissue. Examples include myocardial infarction (MI), ischemic strokes, and malfunction in newly transplanted organs. In transient ischemia, much of the damage is done during reperfusion rather than in the ischemic period. Restoration of blood flow, either spontaneous or achieved

through thrombolytic therapy, is accompanied by tissue damage and destruction that often extend far beyond the margins of the ischemic area. One of the major tissue-damaging factors is C activation. Dead and damaged cells are efficient activators of C and local activation during reperfusion of ischemic tissue will cause further tissue damage, propagating the injury into surrounding viable tissue. In MI, the infarct and surrounding 'penumbra' of damaged but viable tissue contains abundant deposits of C activation products, also detectable in plasma for days after the episode (Kilgore et al. 1994). CRP is also deposited in and around the infarct where it binds to damaged cells and triggers further activation of C (Griselli et al. 1999).

Similar evidence is apparent in stroke where the effects of C activation may be magnified because of the remarkable sensitivity of brain cells to C damage (Singhrao et al. 2000). In transplanted organs, the degree of C activation and tissue damage correlate closely with the ischemic interval between organ harvest and implantation. The involvement of C during the brief window of reperfusion in all these injuries presents an ideal opportunity for the use of anti-C agents. Early studies, using the C-depleting agent cobra venom factor (CVF) showed a marked protective effect when given before reperfusion in a baboon model of MI (Crawford et al. 1988). CVF pre-treatment also markedly increased graft survival in rodent models of heart and kidney transplantation (Thomas et al. 1977; Forbes et al. 1978). CVF is a toxic and highly antigenic agent that inactivates C by depleting the system to exhaustion and it is therefore not suitable for use as a therapeutic. Modern C therapies have also been used in ischemia–reperfusion models. A recombinant soluble form of the C receptor CR1 (sCR1), an efficient inhibitor of C in vivo, markedly reduces infarct volume when given at the time of reperfusion in a rat model of MI (Weisman et al. 1990).

Complement in neurological diseases

Complement has been implicated in diverse disorders of the nervous system, including such conditions as stroke, traumatic injury, demyelinating disorders, and neurodegenerative diseases. A summary of the information from the last two groups of diseases follows.

Demyelination in the central nervous system causes multiple sclerosis (MS), a distressing, progressive disease that causes severe disability and even death in sufferers. The underlying cause of MS remains the subject of debate, although it is now broadly accepted that there is an underlying autoimmune component. T cells infiltrating the areas of pathology in the brain are prime suspects. Indeed, in animal models of MS, disease can be transferred by T cells from affected animals to naïve recipients. A role for C in MS was first suggested by demonstrating C consumption and C activation products in plasma and cerebrospinal fluid (CSF) (Morgan et al. 1984; Mollnes et al. 1987). Others showed C deposition in and around plaques in MS brain (Compston et al. 1989) and demonstrated that myelin in vitro directly activated C via the classical pathway (Liu et al. 1983). Recently, detailed clinical and histopathological studies have divided MS into several subgroups, C activation being a major feature in some but not all the groups (Lucchinetti et al. 2000). Decomplementation or therapy with anti-C agents reduced myelin injury in rodent models of MS, further implicating C in myelin loss (Linington et al. 1989; Piddlesden et al. 1994). Demyelination in the peripheral nervous system causes several related pathologies, the most common of which is the Guillain–Barré syndrome (GBS). A role for C was first suggested from demonstrations of the capacity of peripheral nerve myelin to activate C (Koski et al. 1985). C activation products were found in CSF (Sanders et al. 1986) and peripheral nerve (Hafer-Macko et al. 1996) from GBS patients, and decomplementation inhibited disease in the rodent model of GBS (Vriesendorp et al. 1995).

Taken together, these data make a persuasive case for the use of anti-C therapy in at least some forms of demyelinating diseases. The problem is that none of the currently available agents is suitable for long-term therapy, so treatment in MS will probably have to await the development of better drugs. GBS, unlike MS, is a relatively acute disease, most patients making a complete or partial recovery from the demyelinating episode. Anti-C therapy given early in the course of disease might have particularly beneficial effects and could be undertaken with contemporary agents.

To suggest that the innate immune system contributes to degenerative disorders of the nervous system smacks of heresy, yet there is a substantial and growing body of evidence to support the suggestion. Neurodegeneration underlying Alzheimer's disease and related syndromes is, despite an enormous research effort over the past decade, poorly understood. Many mechanisms have been proposed but none has yet proved to be the key to understanding and preventing loss of neurons. The first suggestion of a role of C came from histological studies that showed deposits of C activation products in and around the plaques and tangles that typify the brain in Alzheimer's disease (McGeer et al. 1991, 1994; Eikelenboom et al. 1992). The β-amyloid peptide that is present in plaques activates C in an antibody-independent manner. These findings have led several workers in the field to suggest that Alzheimer's disease is a low-grade inflammatory disease and that anti-inflammatory or anti-C therapy would slow or reverse cognitive decline in Alzheimer's disease (McGeer and McGeer 1999). Trials of anti-inflammatory agents have begun and time will tell whether this approach is likely to be of benefit. Studies in the many animal models of Alzheimer's disease may also help establish whether C plays a significant role in neurodegeneration.

Complement in iatrogenic syndromes

With increasingly sophisticated interventions, iatrogenic or treatment-caused injuries are becoming more frequent. Here, focus is given to one group of injuries where C is known to have a role and anti-C therapies might prove beneficial.

Numerous interventions involve exposure of blood to a foreign surface in an extracorporeal circuit. In renal dialysis, blood is exposed to the dialyzer membrane, usually made of cellulosic materials such as cuprophane, or polymeric materials such as polysulfone. All these materials are, to a greater or lesser extent, bioincompatible and trigger activation of many plasma effector systems, including C. Activation of C and generation of C activation products, particularly C5a, activates neutrophils and other cells in the plasma and can cause fever, neutropenia, and other unwanted effects. The problem can be circumvented to a degree by choosing the least activating surface or by precoating the dialyzer membrane with either albumin or plasma proteins. Membranes that are used several times are always most activating on first use because of this surface-coating phenomenon. C activation can be reduced by pretreating the membrane with heparin, an inhibitor of C activation. C activation may be even more marked in cardiopulmonary bypass circuits, where not only the extensive surfaces of membranes and tubing, but also the plasma-expanding fluids and the gas–liquid interface in the oxygenator, may all activate C (Mollnes et al. 1991; Mollnes 1997). Secondary activation of neutrophils and other blood cells, and generation of inflammatory cytokines, will contribute to the injury and it is not uncommon for patients coming off bypass to be severely compromised for several days, necessitating prolonged intensive care – the post-bypass syndrome. Again, choice of the least activating system and precoating of circuits with protein and/or heparin may reduce activation in the circuit and minimize iatrogenic injury (Svennevig et al. 1993; Fosse et al. 1994). Studies in vitro and in animal models indicate that administration of anti-C agents during the period of bypass may be of great benefit in reducing the risk of unwanted sequelae (Gillinov et al. 1993; Moat et al. 1993; Finn et al. 1996; Lazar et al. 1999).

COMPLEMENT THERAPIES

It should be clear from the previous sections that an ability to manipulate the C system therapeutically might be of considerable benefit in many diseases. Until very recently, no agents suitable for the inhibition of C in humans were available. Crude methods using agents that consumed C (CVF) or, at high doses, expressed a modest anti-C activity (e.g. low-molecular-weight heparins) had been used in animals with some promising results. However, problems of toxicity, antigenicity, or other unwanted effects rendered such agents unusable in humans. The breakthrough came with the demonstration, in the early 1990s, that an engineered recombinant soluble form of a natural C regulator, CR1, was a powerful inhibitor of C activation both in vitro and in vivo (Weisman et al. 1990). Over the last decade, the field of C therapies has exploded and we now have numerous agents on the verge of application in the clinic (Table 4).

There are various considerations to be taken into account when developing anti-C therapies. These include the side effects of long-term systemic inhibition of the C system, choice of the most efficient point at which to inhibit C, rapid clearance of reagents in vivo, and the high cost of biological therapies. Inhibition of C will render the recipient less capable of fending off bacterial infections, may predispose to immune complex diseases, and could cause defects in immune tolerance. Although short-term inhibition, as might be used in acute situations, is unlikely to cause many problems, long-term therapy for chronic conditions might well do so. Judicious choice of the stage of inhibition in the C pathway may reduce the risk. Given that so many of the 'physiological' effects of C are mediated by C3 and its fragments, agents that inhibit after C3 cleavage are unlikely to cause significant detrimental effects. Considerations of half-life and cost also relate primarily to long-term uses. A variety of strategies has been proposed to create longer-acting, cheaper anti-C agents for use in chronic conditions.

Recombinant soluble forms of the naturally occurring C regulators

As noted above under Complement therapies, sCR1 (TP10), generated by removing the membrane-anchoring domain from CR1, led the new wave of anti-C agents and has proved efficacious in a large and diverse range of disease models. sCR1 inhibits formation of the C3 and C5 convertase enzymes, preventing C3b opsonization, C5a generation, and MAC formation. It has been awarded 'orphan drug' status from the Food and Drugs Administration (FDA) for therapy of adult respiratory distress syndrome (ARDS) and as a treatment for infants undergoing cardiac surgery (Zimmerman et al. 2000; Rioux 2001). Numerous modifications have been made to sCR1 to alter or improve efficacy in vivo. Removal of the amino-terminal seven SCRs generates a reagent termed sCR1[desLHR-A], an alternative pathway-specific inhibitor which permits continued classical pathway activation for immune complex handling (Murohara et al. 1995; Scesney et al. 1996). Both sCR1 and sCR1[desLHR-A] have been derivatized with the sialyl Lewis^x (sLe^x) carbohydrate antigen, a ligand for E- and P-selectins (Rittershaus et al. 1999). These agents

Table 4 *Current C therapies*

Agent	History and status	Pros	Cons
sCR1 (TP10)	The first of the new generation of anti-C therapies; used in many models; first in clinical trials. Now superseded?	Proof of concept; works across species	Expensive Systemic
SLe^x-sCR1 (TP20)	First of the modified sCR1 agents; binds endothelium at sites of inflammation, tested in many models, no clinical trial	May be more 'site specific' than sCR1	Expensive Systemic
APT-070	Truncated, membrane-targeted sCR1 derivative, tested in several models, early stages of clinical trials	'Site specific'?, retained at injection site? Made in bacteria so cheaper?	Unproven Systemic
h5G1.1 and derivatives	Recombinant scFv of anti-C5 monoclonal antibody (mAb); permits opsonization; effective in several models; well advanced in clinical trials	Long half-life compared with sCR1; relatively cheap; nearest to the clinic. The mAb-based therapies well accepted	Systemic
C5aR antagonists	Several agents vying for this niche; attractive drug target; many positive results in models	Small molecule agents (peptides and others); may be inexpensive, may work orally or topically	Unproven
Small molecule antagonists of components	Numerous agents, best explored is the C3 inhibitor Compstatin; good results in models, no trials	May be inexpensive, may be active orally or topically	Unproven

For references to these agents, see the text.

showed enhanced efficacy in murine models of stroke and ischemia–reperfusion injury and rat models of ARDS, probably as a result of the combined activities of localizing C inhibition to the endothelial cell membrane and blockade of leukocyte adhesion to the endothelium (Huang et al. 1999; Mulligan et al. 1999; Schmid et al. 2001).

A truncated form of sCR1, comprising the amino-terminal three SCRs, has been successfully expressed and refolded from *Escherichia coli* and shown to retain activity (Dodd et al. 1995; Mossakowska et al. 1999). Chemical modification of the carboxy-terminus with an 'addressin', comprising a membrane-targeting peptide and a lipophilic acyl chain, myristate, results in a powerful regulator of C activation (Smith and Smith 2001). The 'addressed' reagent, termed APT070, is 100-fold more active than the parent molecule and has proved to be beneficial in various models of disease including arthritis and ischemia–reperfusion (Linton et al. 2000).

Recombinant, soluble forms of MCP and DAF have also been generated and proved effective at inhibiting C in vitro and in various models of C-mediated disease (Moran et al. 1992; Christiansen et al. 1996b). Unlike sCR1, which has both cofactor and decay-accelerating activity, sDAF and sMCP have only one anti-C activity. The sCR1 form is a more effective fluid phase inhibitor than either sDAF or sMCP and mixtures of the two agents are more effective than either alone, illustrating cooperative activities (Christiansen et al. 1996a). A hybrid comprising sMCP fused to the amino terminus of sDAF, termed C activation blocker-2 (CAB-2), is a potent inhibitor both in vitro and in models (Higgins et al. 1997; Kroshus et al. 2000).

The membrane MAC regulator, CD59, has also been generated as a soluble form (sCD59) (Sugita et al. 1994; Quigg et al. 2000). However, sCD59 is a poor inhibitor of C in whole serum, a consequence of its short plasma half-life and tendency to bind plasma lipoproteins.

Antibody-based therapies

Antibodies targeting either C components or C receptors have attracted considerable attention as potential therapies, buoyed by the many other antibody-based agents that have already reached the clinic. Perhaps the most successful of the current anti-C agents is an antibody, h5G1.1, that binds C5 and prevents its enzymatic cleavage (Thomas et al. 1996). This agent does not prevent cleavage of C3, so opsonization of pathogens and immune complexes with C3b can occur, whereas generation of C5a and MAC are prevented. A recombinant, humanized, single-chain Fv of this antibody has been used in clinical trials for treatment of ARDS and ischemia–reperfusion injury, and has been particularly successful in cardiopulmonary bypass at reducing the post-bypass syndrome (Thomas et al. 1996; Fitch et al. 1999). Other antibodies have been generated that target other components of the terminal pathway (Rollins et al. 1995), C fragments such as C3a and C5a (Czermak et al. 1999), or the receptors for these fragments (C3aR, C5aR) (Morgan et al. 1993).

Small molecule inhibitors

A different approach to the generation of anti-C agents has been to seek small molecule inhibitors. Such agents

potentially have major advantages over biological agents in terms of cost and ease of administration but are not without problems. Several groups have probed libraries of phage-display random peptides to identify agents. This approach has identified a cyclic 13-residue peptide, termed compstatin, which binds C3 and prevents its cleavage by convertase enzymes (Sahu et al. 1996; Nilsson et al. 1998; Fiane et al. 1999), and peptides that inhibit C1 activation (Roos et al. 2001). Other approaches have identified small molecule serine protease inhibitors specifically targeting C1s and factor D (fD) in the classical pathway and alternative pathway, respectively (Buerke et al. 1995; Kimura et al. 1998; Ueda et al. 2000). Numerous small molecule agents, peptide and non-peptide, targeting the C5aR (C5aR antagonists) have been developed and shown to be effective in models of ischemia–reperfusion injury and shock, and in the reverse passive Arthus reaction (Heller et al. 1999; Short et al. 1999; Riley et al. 2000; Strachan et al. 2001). Therapeutic effects have been demonstrated with some of these C5aR antagonists after oral or topical administration; such agents may be important therapeutic agents for the future.

CONCLUDING REMARKS

Complement, now over 110 years old, has finally come of age. The influence of C in many different areas of immunology and cell biology is now being realized; in fact, one would be hard pressed to identify a more protean part of the immune system. It should be clear from what has gone before that C is core to innate immunity, casts a large influence over adaptive immunity, plays key roles in cell death and clearance of debris, and is a major pathological factor in diverse diseases. The field is now ready to shed its slightly shady past and is prepared to be accepted as a 'respectable' branch of immunology. Welcome it with open arms!

Antimicrobial peptides: defensins and cathelicidins

ROBERT I. LEHRER AND TOMAS GANZ

Defensins	1	Concluding remarks	11
Cathelicidins	8	References	11

Leukocytes, inflammatory exudates, and many secretions exert antimicrobial activity that results from the individual and combined effects of their constituents. The responsible components may include enzymes such as lysozyme, metal-binding proteins such as lactoferrin, highly cationic proteins such as histones or fragments thereof, various lipopolysaccharide (LPS)-binding molecules, and antimicrobial peptides. Surprisingly, there is large interspecies variation in the number and nature of these effector molecules, and considerable cell-to-cell and tissue-to-tissue variation within any given species. This chapter covers two large groups of antimicrobial peptides found in mammals: defensins and cathelicidins.

We define antimicrobial peptides as molecules with fewer than 100 amino acids, which exist in host defense settings, and exhibit antimicrobial activity under locally prevailing conditions. Antimicrobial peptides are ancient weapons of host defense, and many have been found in organisms that antedate mammals. A partial roster of these antimicrobial peptides includes the microhalocins of Archaebacteria (O'Connor and Shand 2002), the bacteriocins (Diep and Nes 2002), and lantibiotics (Pag and Sahl 2002) of Eubacteria, the amoebapores of protozoa (Leippe 1999), the cysteine-rich 'defensins' of plants (Broekaert et al. 1995; Garcia-Olmedo et al. 1998; Thomma et al. 2002), and numerous peptides of insects and other invertebrates (Dimarcq et al. 1998; Bulet et al. 1999). Readers seeking a broader view of antimicrobial peptides should consult the cited references, and the many fascinating studies in *Drosophila* spp. (Hoffmann and Reichhart 2002; Tzou et al. 2002).

Much information about mammalian antimicrobial peptides has come from studying the leukocytes found in blood and their precursors in the bone marrow. In humans, the most abundant blood leukocytes are granulocytes – cells with cytoplasm that contains multiple granules. Those most important for antimicrobial defense are variously called neutrophils, 'polys' – shorthand abbreviation of their more formal (and formidable) name: polymorphonucleated neutrophilic granulocytes (PMN). The several thousand small granules within the cytoplasm of each human PMN are tiny storage organelles that contain a variety of peptides and proteins, many with antimicrobial properties. The PMNs of rabbits and chickens have such an abundance of highly cationic peptides in their granules that they appear eosinophilic after conventional blood staining (Wetzel et al. 1967; Kogut et al. 1994; Stabler et al. 1994). These cells, often called 'heterophils' or pseudo-eosinophils, are the functional equivalent of the human PMN.

The cytoplasmic granules in human PMNs are of several types, and they behave differently after the cell ingests microbes or detects molecular signals (e.g. *N*-formylated peptides, complement-derived chemotaxins, etc.) denoting their presence. The PMN's primary ('azurophil') granules are formed early during its differentiation in the bone marrow, and these granules largely transfer their contents to intracellular phagocytic vacuoles. The secondary ('specific') granules of PMNs form after the azurophil granules and contain a substantially different set of proteins and peptides. Most of the contents of specific granules are secreted outside the PMN; whereas defensins are stored in azurophil

granules, cathelicidins are stored in the specific granules. As a result of these storage and delivery patterns, defensins and cathelicidins operate in environments that differ in ionic composition, pH, local peptide concentration, presence or absence of serum proteins, etc. Not surprisingly, they have different structures and properties.

DEFENSINS

Defensins constitute a large and growing family of antimicrobial peptides, the members of which have been identified in mammals, birds, and some reptiles. All defensins have a largely β sheet structure that is stabilized by a tri-disulfide framework formed by six paired cysteines. These peptides were initially called 'lysosomal cationic proteins' and were first noticed in studies of rabbit and guinea-pig granulocytes (Zeya and Spitznagel 1966a, 1966b). Technical advances in peptide purification and characterization allowed more detailed chemical descriptions of the rabbit molecules by the mid-1980s (Lehrer et al. 1983; Selsted et al. 1983, 1984), and homologous peptides were identified soon thereafter in human leukocytes (Ganz et al. 1985; Selsted et al. 1985a). Defensins are also produced by epithelial cells (Ouellette et al. 1989) and may contribute prominently to innate mucosal host defense in the respiratory, reproductive, and gastrointestinal tracts (Huttner and Bevins 1999).

Structural considerations

Cysteine-rich antimicrobial peptides that are also called defensins occur in the hemolymph of insects (Boman and Hultmark 1987; Hoffmann et al. 1996) and in various plant tissues (Broekaert et al. 1995; Garcia-Olmedo et al. 1998). In antifungal plant defensins, the peptide backbone is stabilized by four cystine disulfide bonds, rather than the three intramolecular S-S bonds present in mammalian defensins. At least 13 putative defensin genes have been identified in *Arabidopsis thaliana*, and these genes may encode 11 different defensins. The evolutionary relationship of insect and plant defensins to those of vertebrates is uncertain.

A short α-helical domain is present in several human β defensins (Hoover et al. 2000; Sawai et al. 2001; Schibli et al. 2002), insect defensins (Cornet et al. 1995; Bulet et al. 1999), and some plant defensins (Fant et al. 1998). However, the disulfide connectivity of insect defensins (cysteines 1–4, 2–5, 3–6) differs from that of any mammalian defensin. Structures of several α and β defensins have been solved by two-dimensional nuclear magnetic resonance (NMR) and X-ray crystallography (Selsted et al. 1985a; Bach et al. 1987; Pardi et al. 1988, 1992; Zhang et al. 1992; Zimmermann et al. 1995; Hoover et al. 2000; Sawai et al. 2001; Schibli et al. 2002). Although the cysteine spacing of mammalian α and β defensins differs considerably, and their connectivity differs slightly (Figure 1), all contain a triple-stranded β sheet with a distinctive 'defensin fold'. The six cysteines of α defensins are linked in a 1–6, 2–4, 3–5 pattern (Selsted and Harwig 1989), whereas a 1–5, 2–4, 3–6 pattern is found in β defensins (Tang and Selsted 1993). As cysteines 5 and 6 are positioned right next to each other in both α and β defensins, this connectivity difference has little impact on their backbone structure (Zimmermann et al. 1995). Several human β defensins and insect defensins are illustrated in Figure 2. Recent forays into the human genome have revealed a large number of β-defensin genes and/or pseudogenes, the integrity and functionality of which remain to be determined (Schutte et al. 2002).

Defensin evolution

The presence of β-defensin-like peptides in snake venom (e.g. growth-arresting peptide and crotamines (Zhao et al. 2001b)) suggests that some of these host defense peptides can be used against targets considerably larger than bacteria, fungi, and viruses. Three members of a structurally unique defensin subfamily were recently identified in leukocytes and bone marrow of the rhesus macaque (Tang et al. 1999; Leonova et al. 2001). Called rhesus theta (θ) defensins (RTD), these molecules are cyclic octadecapeptides with three intramolecular disulfide bonds and a β-sheet structure (Tang et al. 1999). Their production involves post-translational splicing of two nonapeptide segments, each derived from a truncated, α-defensin-like precursor (Figure 3). The adjoining chromosomal locations of their genes, and

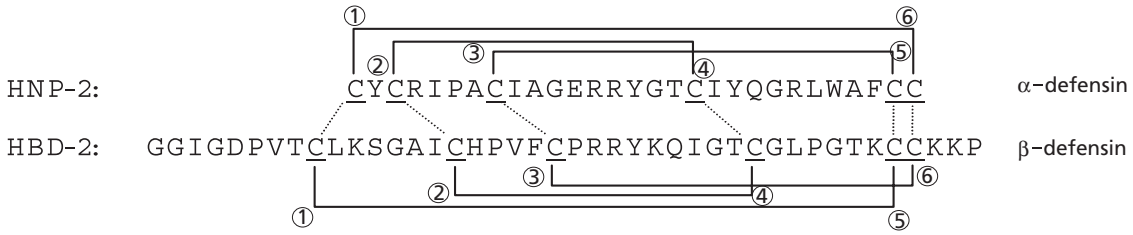

Figure 1 *α and β defensins. Human neutrophil peptide-2 (HNP-2), an α-defensin, and human β-defensin-2 (HBD-2) are shown. Both contain six cysteines, that have been numbered from the amino terminus. The cysteines of α and β-defensins have a different pairing pattern, as described in the text, and β defensins are somewhat larger.*

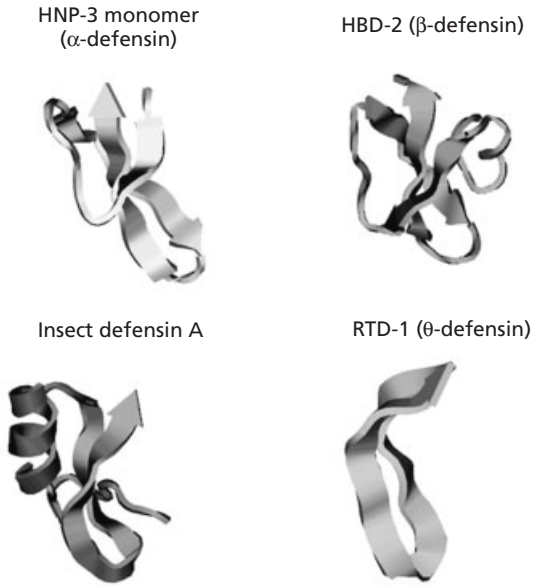

Figure 2 *Backbone structures of four different types of defensins. The α-, β-, and θ-defensin peptides expressed by animals arose from a common ancestral gene, the relatedness of which to insect defensin genes is unknown.*

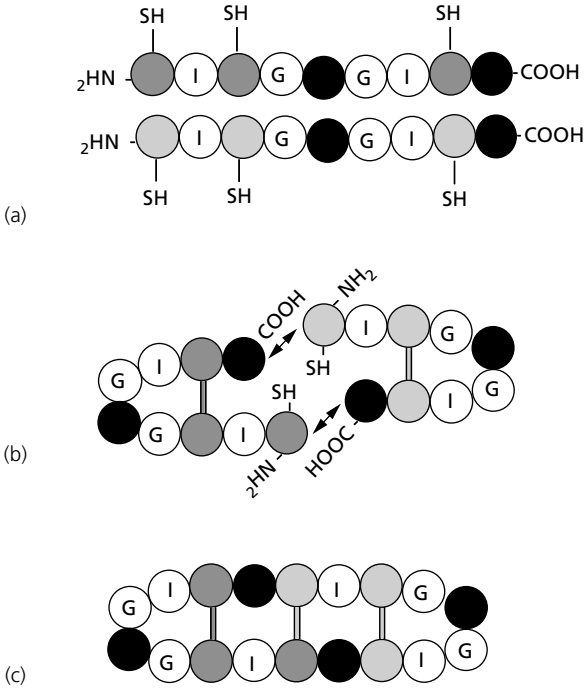

Figure 3 *Making a θ defensin. In these cartoons, each circle represents an amino acid residue identified either by single letter code (G, glycine; I, isoleucine) or color (black, arginine; gray, cysteine). The two identical nonapeptides in* **(a)** *correspond to a portion of the retrocyclin-1 precursor described in the text. In* **(b)**, *the double-headed arrows show where these nonapeptides will be spliced to form the cyclic octadecapeptide (θ defensin) shown in* **(c)**. *The events shown in this figure are illustrative – the actual intracellular biochemistry of θ-defensin production remains to be established.*

the structural similarity of their peptides or peptide precursors, make it virtually certain that α, β, and θ defensins arose from a common ancestral gene (Liu et al. 1997).

Just as the existence of β defensins in birds and reptiles identifies them as the oldest vertebrate defensin subfamily, the initial appearance of θ defensins in Old World Monkeys marks them as the youngest subfamily. We have identified intact *DEFT* (θ defensin) genes in several Old World Monkeys, siamangs (a lesser ape), and orangutans. In contrast, we found that the corresponding *DEFT* genes of humans, gorillas, and chimpanzees contained a mutation (a stop codon in the signal sequence) that prevented translation. From phylogenetic considerations, we infer that a hominid ancestor who lived between 7.5 and 10 million years ago sustained the mutation that removed θ defensins from the innate host-defense arsenal of his or her descendants. θ defensins are interesting for many reasons, not the least of which is their ability to inhibit the uptake of HIV-1 by otherwise susceptible $CD4^+$ target cells (Cole et al. 2002).

Variability of expression

Although α- and/or β-defensin peptides probably exist in all mammals and birds, relatively few different species have been studied to date. Defensin expression by neutrophils demonstrates remarkable interspecies variability. Whereas the PMNs of humans, rats (Eisenhauer et al. 1989, 1990), and rabbits contain large amounts of α defensins, the PMNs of cattle (Selsted et al. 1993) and chickens (Harwig et al. 1994) have only β defensins, and murine PMNs contain neither α nor β defensins. Several other mammals, including pigs, sheep, goats, and horses, have PMNs that lack defensins. In some of these animals (e.g. pigs and sheep), the PMNs may compensate by expanding their cathelicidin content. In other species, PMNs may rely more on oxidative microbicidal mechanisms mediated via reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (Wientjes and Segal 1995) and/or inducible nitric oxide synthase (MacMicking et al. 1997; Sethi and Dikshit 2000).

The highest local concentrations of defensins (>10 mg/ml) occur in the storage organelles (granules) of leukocytes (Ganz 1987). When leukocytes ingest microbes and sequester them within phagocytic vacuoles, fusion of the granule and vacuole membranes deposits the defensins and other contents directly on the captured microbe. As little 'empty' space exists in phagocytic vacuoles, ingested microbes are exposed to very high peptide concentrations which, by favoring defensin oligomer/multimer formation, could enhance their efficacy and override any inhibitory effects of the intravacuolar ionic milieu or pH.

Paneth cells are specialized host-defense cells that occupy the base of the crypts in the small intestines of humans and other omnivores. Their prominent secretory granules contain α defensins, and these peptides are secreted into the narrow crypt lumen after bacteria or bacterial LPS enters the intestine. Paneth cell secretion is also stimulated by cholecystokinin or parasympathomimetic agents (Satoh 1988; Satoh et al. 1989). Intestinal crypts are the exclusive sites where the epithelial cells that line intestinal villi arise. Consequently, anticipatory secretion of defensins by Paneth cells may protect this vital cell nursery from adventurous microbes that enter the crypts. Given the crypt lumen's narrow dimensions, its post-secretory defensin concentration may resemble that found in PMN phagocytic vacuoles (Ayabe et al. 2000).

Skin keratinocytes and various epithelia produce β-defensins constitutively (Valore et al. 1998) or in response to infection or inflammation (Harder et al. 2001; Schonwetter et al. 1995). On average, the concentration of defensins in these epithelia ranges from 10 to 100 μg/ml (Harder et al. 1997; Shi et al. 1999), but may be much higher locally if the peptides are unevenly distributed. In the human skin, human β-defensin-2 production is massively induced by interleukin-1 released from myeloid cells, and is secreted by lamellar bodies into the intercellular space between differentiating keratinocytes (Liu et al. 2002, 2003; Oren et al. 2003). Keratinocytes that overexpress human β-defensin-1 (HBD-1) show greater expression of keratin 10, a differentiation marker, suggesting that HBD-1 may enhance cell keratinocyte differentiation (Frye et al. 2001).

Although murine PMNs lack leukocyte defensins and rat PMNs have them in abundance, the Paneth cells of both species express multiple α defensins, and their epithelial tissues express many β defensins. In some cases, defensin expression may be induced by a combination of a specific cell type and local environment. Inflammatory macrophages are leukocytes that arise from circulating blood monocytes which differentiate under the influence of local tissue signals. Rabbit alveolar (lung) macrophages contained two α defensins (NP-1 and NP-2) in amounts approaching their abundance in rabbit neutrophils, but no defensins were present in peritoneal macrophages from the same animals (Ganz et al. 1989). Although defensin expression in monocytes, macrophages, and lymphocytes of some mammals can be detected by highly sensitive techniques (Ryan et al. 1998; Agerberth et al. 2000; Duits et al. 2001), high levels of defensins within macrophages have been documented only in the rabbit alveolar macrophage (Patterson-Delafield et al. 1980, 1981). Some peculiarities in the variable pattern of defensin expression may be driven by evolutionary pressure from species-specific or organ-specific pathogens.

Antimicrobial and antiviral properties

Most defensins display microbicidal activity against bacteria and fungi, especially if tested under low ionic strength conditions or with low concentrations of divalent cations, plasma proteins, or other interfering substances (Selsted et al. 1985b; Lehrer et al. 1988). Under optimal conditions, defensin-mediated antimicrobial activity is evident at peptide concentrations in the low micromolar range. Increasing the medium's salinity inhibits the antimicrobial efficacy of defensins against many organisms, especially gram-negative bacteria. Certain plasma proteins bind defensins, e.g. α_2-macroglobulin (Panyutich and Ganz 1991), and are also inhibitory. In general, metabolically active bacteria are much more sensitive to defensins than bacteria made inactive by nutrient deprivation or metabolic inhibitors. Some bacteria, e.g. *Brucella* and *Burkholderia* spp., are intrinsically resistant to defensins and many other antimicrobial peptides (Martinez et al. 1995; Jones et al. 1996).

Infection by enveloped viruses, such as herpes simplex and vesicular stomatitis virus (Lehrer et al. 1985; Daher et al. 1986), and by adenovirus, a nonenveloped virus (Gropp et al. 1999; Bastian and Schafer 2001), is inhibited by defensins. Human α defensins HNP-1, -2, and-3 suppressed HIV replication (Nakashima et al. 1993). Their production by αβ-$CD8^+$ T cells may promote resistance to developing AIDS (Zhang et al. 2002).

As some defensins are cytotoxic to mammalian cells in vitro (Lichtenstein et al. 1986, 1988; Lichtenstein 1991; Zhang et al. 2001), especially when they are tested at high concentrations or under serum-free conditions, it is possible that defensins may contribute to inflammatory tissue damage in vivo.

ANTIMICROBIAL MECHANISMS

An indicator bacterium (*Escherichia coli* ML-35) (Lehrer et al. 1989) and the K562 mammalian cell line (Lichtenstein 1991) became permeable to small molecules, such as sugars and trypan blue, after being treated with α defensins. In the bacteria, the onset of permeabilization coincided with inhibition of RNA, DNA, and protein synthesis, and decreased bacterial viability as assessed by colony-forming assays. In the K562 cell line, permeabilized cells could be rescued for up to 1 h by removing the defensin. There is evidence that intracellular sites of action also contribute to cell death (Gera and Lichtenstein 1991; Lichtenstein 1991).
